To illustrate the use of the foregoing relations, the following transmission-line constants are assumed: $R=16$ ohms, $X=80$ ohms, $B=500\times10^{-6}$ mhos, and $E=138$ kv (actual sending end voltage).

Using equation 11 and solving for E_{OC}

$$E_{OC}=\frac{2E\times10^6}{500\sqrt{(16)^2+\left(80-\frac{2\times10^6}{500}\right)^2}}$$

$$=1.02E$$

since E is 138 kv, then

$E_{OC}=1.02\times138=141$ kv = base voltage

Using equation 12 and solving for Z_D

$$Z_D=\frac{-J\frac{2\times10^6}{500}(16+J80)}{16+J\left(80-\frac{2\times10^6}{500}\right)}\text{ ohms}=16.3+J81.5\text{ ohms}=83\text{ ohms}=\text{base ohms at }X/R=5$$

Using equation 13 and solving for base kva

$$\text{base kva}=\frac{(141)^2\times1{,}000}{83}=239{,}000$$

If a load of 50,000 kw at 95-per-cent power-factor lagging were transmitted through the line, the pu value of the load would be

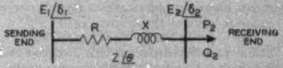
$$P_2=\frac{50{,}000}{239{,}000}=0.209\text{ pu}$$

$$Q_2=\frac{0.329\times50{,}000}{239{,}000}=0.069\text{ pu}$$

where 0.329 is the tangent of the power-factor angle.

Appendix II. Fundamental Power and Reactive-Flow Equations for a Unit Impedance Circuit

The following two equations have been developed in reference 4 for the following circuit configurations



$$P_2=-\frac{E_2^2\cos\theta}{Z}+\frac{E_1E_2}{Z}\sin(\delta_{12}+\alpha) \tag{14}$$

$$Q_2=-\frac{E_2^2\sin\theta}{Z}+\frac{E_1E_2\cos(\delta_{12}+\alpha)}{Z} \tag{15}$$

where

P_2 = receiving power, pu
Q_2 = receiving reactive flow, pu
E_1 = sending-end voltage, pu
E_2 = receiving-end voltage, pu
Z = circuit impedance, pu
δ_1 = angle of voltage E_1
δ_2 = angle of voltage E_2
δ_{12} = angular difference between E_1 and E_2
θ = angle of impedance Z
α = 90 degrees $-\theta$

All quantities in equations 14 and 15 are magnitude quantities and not in phasor form. These equations are general and may be used for a unit impedance circuit of the type described in the paper. Letting $E_1=E_{oc}=1.0$ pu and $Z=Z_D=1.0$ pu, equations 14 and 15 are rewritten

$$P_2=-E_2^2\cos\theta+E_2\sin(\delta_{12}+\alpha) \tag{16}$$

$$Q_2=-E_2^2\sin\theta+E_2\cos(\delta_{12}+\alpha) \tag{17}$$

In these equations, positive load power and reactive flow is taken as flow toward the load and away from the receiving terminal of the circuit.

Equations 16 and 17 may be combined so as to eliminate the variables sin $(\delta_{12}+\alpha)$ and cos $(\delta_{12}+\alpha)$. This is done by squaring equations 16 and 17 and adding the two squared equations, which results in

$$E_2^2=(P_2+E_2^2\cos\theta)^2+(Q_2+E_2^2\sin\theta)^2 \quad (18)$$

where

$$\cos\theta=\frac{R}{Z_D}=R\text{ pu, since }Z_D=1.0$$

$$\sin\theta=\frac{X}{Z_D}=X\text{ pu, since }Z_D=1.0$$

The use of equation 18 may be illustrated using the network in Fig. 3, where it was shown that the network viewed from bus R' can be replaced by a unit impedance equivalent as represented in Fig. 4. It was determined that

$E_1=E_{OC}=124$ kv $=1.0$ pu

$Z_D=1.0$ pu on 124 kv and 181,000-kva base of $X/R=14.9$

Assume that

$P_2=20$ megawatts or 0.111 pu on 181,000-kva base

$Q_2=0.5P_2=10$ megawatts or 0.056 pu on 181,000-kva base

and solve for E_2 using equation 18

$$R^2+X^2=Z_D^2=1.0$$

$$\frac{X}{R}=14.9$$

$$R^2+(14.9R)^2=1.0$$

$$R=0.067\text{ pu}$$

$$X=14.9\times0.067=0.998\text{ pu}$$

Substituting known quantities into equation 18

$$E_2^2=(0.111+0.067E_2^2)^2+(0.056+0.998E_2^2)^2$$

Perhaps the simplest way to solve this expression for E_2 would be to substitute several trial values for E_2 into the right side of the equation, solve for E_2, and interpolate for the exact correct value for E_2. However, it was found, using power-reactive diagrams, that E_2 was 115 kv. This is equal to 115/124 or 0.929 pu of E_{OC}. Substuting this value in the right-hand side of the expression for E_2

$$E_2^2=(0.111+0.067\times\sqrt{0.929})^2+(0.056+0.998\times\sqrt{0.929})^2$$

$$E_2^2=0.868$$

$$E_2=0.93$$

This value agrees closely with the substituted value and is the correct value for all practical purposes.

Discussion

R. D. Goodrich (Bureau of Reclamation, Denver, Colo.): This paper forms a logical link between Thévenin's theorem and circle diagram theory. Now that the connection between the two has been demonstrated it will be easy for others to suggest improvements and refinements, which are, of course, valuless without the original paper.

One more or less obvious suggestion is to utilize preplotted circles with auxiliary loci for constant watts, constant power factor, or constant real or reactive loss located on the receiving-end diagram. These loci can all be derived for constant sending-end voltage, and afford means of plotting families of auxiliary curves of, e.g., substation voltage versus substation load for various values of power factor. A number of equations for these loci are given elsewhere.[1] The data for the constant loss circles are:

Real power loss

1. Center on the B line at the distance $P_{SL}^1\cos\beta$ from the center of the power circles
2. Radius $R_{PL}=P_{SL}^1\sqrt{\cos^2\beta+P_L/P_{SL}^1-P_S^1/P_{SL}^1}$
3. P_L=loss in per unit on system base $P_{SL}^1=e_S^2/(\boldsymbol{AB})_{RP}$

Reactive power loss

1. Center on the B line at the distance $Q_{SL}^1\sin\beta$ from the center of the power circles
2. Radius $R_{QL}=Q_{SL}^1\sqrt{\sin^2\beta+Q_L/Q_{SL}^1-Q_S^1/Q_{SL}^1}$
3. Q_L=loss in per unit on system base $Q_{SL}^1=e_S^2/(\boldsymbol{AB})_{IP}$

Note that the real power loss circle shows that power is delivered to the substation with minimum loss if the reactive load is held constant at one particular value.

A word of caution is in order concerning the use of the diagram: Since Thévenin's equivalent was developed from a loaded system with certain voltages at various points in the system, results are rigorously correct only when those voltages are maintained at their original values. Both the internal voltage and internal impedance of the equivalent depend on the assumption that the loads on the system are constant impedances. But they appear in the original system representation as constant power devices supposedly independent of voltage level. Consequently deviations from the original voltage levels will cause erroneous changes in loads with a consequent error in results. This phenomenon is a familiar one in any application of an equivalent circuit "out of context."

REFERENCE

1. A UNIVERSAL POWER CIRCLE DIAGRAM, Ralph D. Goodrich, Jr. *AIEE Transactions*, vol. 70, pt. II, 1951, pp. 2042–49.

J. R. Curtin (Bonneville Power Administration, Portland, Oreg.): This paper nicely formalizes a technique which we have occasionally found very convenient in predicting the effect of single load additions or changes to a complex network. Even though an analyzer has been in use on the Bonneville system, it is not always convenient to use it to answer specific questions concerning load changes at a given point. It is easily apparent that the technique described can be very valuable to utilities having only occasional access to analyzers if the Thévenin equivalents of busses are listed for future reference.

At times we have even used the system impedance from short-circuit studies, adjusted for system impedance angle. At points remote from generation, the effect of generator subtransient reactance and generator bank reactance on the total impedance is often negligible and can sometimes be satisfactorily corrected for by reducing the system to a mesh between major generation busses, then eliminating generator and generator bank impedance. Nearby synchronous condensers will, of course, spoil the theory but that is an exception to the conditions stated in the paper.

R. M. Butler: The comments of Mr. Goodrich and Mr. Curtin are very much appreciated as they have shown ways to increase the usefulness of the method described in the paper.

Mr. Goodrich has offered a word of caution indicating that Thévenin's theorem requires all loads within the network other than the load in question to be treated as constant impedance loads for strict accuracy. Actually, most of the loads on a power system network are voltage regulated and therefore tend to be independent of voltage variations occurring in the network. Fortunately, an increase of 20 or 30 per cent in the power and reactive components of load at a given point on a network will have a small effect on the voltage levels at most of the other loads connected to the same network. The only exception would be for a condition where the load in question is electrically close to another of about equal size. Even for this condition, it has been found that the error in predicting voltage regulation usually will be quite small. I have concluded that for all practical purposes it does not matter whether the loads, which are a part of equivalent impedance, are of the constant impedance or constant kva type. Since this tends to be borne out by tests on a network analyzer, I concur with Mr. Goodrich's word of caution with the added comment that usually the error produced by the existence of constant kva load will be very small and can be neglected.

Mr. Curtin indicated that for load points electrically remote from generation it is quite permissible to use the short-circuit current as determined from 3-phase fault studies. This would seem to be quite reasonable since the generator transient reactances are a very small percentage of the total equivalent impedance to the load in question. Furthermore, for voltage regulation studies in a distribution system, the effect of generator and step-up transformer impedances is of negligible value as compared with the distribution substation transformer impedance. Hence, the suggestion of using the short-circuit current as determined from fault studies would seem to be a good way to simplify the determination of base quantities.

In using the methods described in the paper, it is necessary to know what the open-circuit voltage E_{OC} is at the load point in question. It would appear that the only way to obtain this value would be to measure it on an a-c calculating board. As mentioned in the paper, analyzers are not always available for this purpose. One way to avoid the necessity of using an analyzer to obtain E_{OC} is to assume that the presently existing peak load in question is part of the calculated equivalent impedance Z_D. Then E_{OC} is simply the voltage corresponding to the presently existing peak load. This voltage can be measured in the field. This approach is correct if it is assumed that the peak load voltage in the future will be either equal to or lower than this value next year. A prediction of next year's peak load voltage must then be based upon the additional increment of load that will be added between now and next year at the load point in question.

One of the biggest timesavers in the use of the methods described in the paper is to have a precalculated circle diagram template available for use. Such a template can be made to include constant voltage circles ranging from 1.10 to 0.80 pu in steps of 0.01 pu. Having such a template will avoid the necessity of reproducing circle diagrams many times as each new problem appears.

I have found that the methods described in the paper for predicting voltage regulation using the circle diagram template have been of considerable value in predicting the improved voltage conditions resulting from the application of capacitors and voltage regulators to points in power systems where such improvement is needed. It is hoped that utility engineers will also find this method to be of value.

Automatically Switched Capacitors in Steps on a Single Distribution Feeder

W. C. FOWLER
MEMBER AIEE

C. W. THOMAS
NONMEMBER AIEE

THE benefits deriving from the connection of static capacitors to the lines of the utility system are well established.[1,2] The disadvantages of leaving them connected at undesirable times are apparent, with the result that many installations utilize varied types of switching and control functions.[3] The maximum benefits are achieved by having capacitors located at the closest possible point to the equipment calling for reactive component of load. Some variation from this ideal may be used to take advantage of the voltage-correcting ability of the capacitors. Over-all economic factors usually determine the exact point of installation of a specific bank of capacitors.

Requirements for control of switched banks have resulted in rather large concentrations at substations. This frequently demands expensive circuit breakers and switchgear to perform the switching functions. The great disadvantage is in failure to make use of the full benefits along the lines of the distribution feeder to the approximate area of the load being delivered. Much has been accomplished in this direction by the use of time switches for control purposes, but these fail to recognize variations of the electric load which require unscheduled switching. Other forms of control are being used, but not to the extent of taking full advantage of capacitors on the feeder lines.

New forms of control units are available in which the time delay before switching is increased logarithmically as the signal strength is decreased to the contact settings. They also provide for the selection of voltage, current, watts, or vars as the signal to be used in switching.[4,5] These units present the possibility of controlling several banks of capacitors on a single feeder and having them selectively switched to fit the circuit conditions at any time.

Procedure for Testing

To investigate these possibilities, it was decided that the 4,160-volt feeder no. 2 in the system of the Public Service Company of Oklahoma offered excellent qualities to determine how well such a program might work. Fig. 1 shows the principal features of this feeder no. 2, with significant items of this test program indicated. Numerous laterals and service points are omitted as not significant.

Control signal for the capacitor bank at point *C* was obtained by measuring the kilovar load at this point on only one phase. It was assumed that unbalance between phases maintained a reasonable proportion at different times. Measurement and control signals at points *B*, *C*, *E*, *F*, and *G* were all definitely obtained from the same phase as was the voltage measurement at point *A*. Control units at *C*, *E*, *F*, and *G* were those having the

Paper 55-91, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 11, 1954; made available for printing November 30, 1954.

W. C. FOWLER is with the Sangamo Electric Company, Fort Worth, Texas, and C. W. THOMAS is with the Public Service Company of Oklahoma, Bartlesville, Okla.

The authors wish to express their appreciation for the services given by other engineers of both Sangamo Electric Company and Public Service Company of Oklahoma. The design and development of the equipment, the installation of all components, the load checks and meter tests, and help in planning these tests involved both companies and numerous men in both organizations.

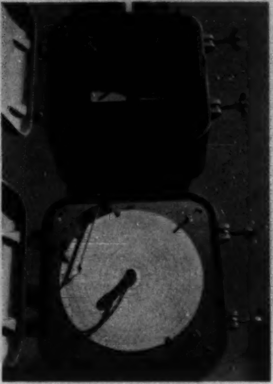

Fig. 2. Voltage control and graphic voltmeter

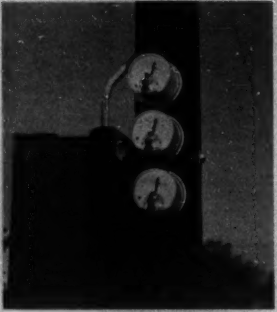

Fig. 3. Voltmeters to observe unbalance between phases

time-delay characteristics previously mentioned. The balance of load between phases was obtained by changing the connection of transformers to the extent that was practical, but no effort was made to construct additional circuits that would have been needed to divide the heavy loads found on a single-phase lateral. Voltage at the substation is maintained to approximately constant values by the switching of large banks of capacitors by the operator in that station.

Loads on the circuit consist of a mixture of industrial, small commercial, and residential customers. The first customer on the feeder is connected immediately after the regulator station, there being only one small transformer bank ahead of point *C* where reactive load is measured for control of the first capacitor bank. Special attention was given to important industrial loads at *M* and *N* and to a single-phase lateral at *L* which has become loaded with window-type air conditioners.

INSTRUMENTATION

Particular care was given to the instrumentation at all significant points. Steady-state voltage was measured with graphic thermal voltmeters at points *A*, *B*, *C*, *E*, *F*, and *G*. Where used with a control device at a capacitor installation, as in Fig. 2, the measuring element was connected through the ON contact so that an accurate record of the times of operation was obtained. Fig. 3 shows the installation of three thermal voltmeters with maximum and minimum indicating pointers, as used as point *N*, to show voltage unbalance as it developed.

Additional measurements included thermal graphic records of kilowatt and kilovar load at point *A*, as shown in Fig. 4. Fig. 5 shows the var control unit with graphic varmeter and graphic voltmeter at point *C*. Control circuit was carried one span to the switched capacitor installation on the pole following the location of the measurement point. All voltmeters were repeatedly checked with a portable precision instrument to insure accurate values when making comparisons.

Results

Figs. 6 and 7 show the nature of information obtained from these measurements and controls. Fig. 6(A) shows the results with some line-drop compensation for resistance set in the regulator, although all reactive compensation was removed. Fig. 6(B) illustrates the operation with no line-drop compensation in the regulator, with output of the regulator set for a fixed bandwidth of $124^{1}/_{2}$ to 126 volts. The voltage-controlled capacitors provided steps in voltage at each point, with the regulator acting as a vernier to bridge these steps. Fig. 7 shows voltage charts from four of the stations during the time represented by Fig. 6(B). With this combination, excellent results were obtained with bandwidths and voltage spreads less than either regulator or switched capacitors alone would achieve. Fig. 6(C) demonstrates operation that would result with no regulator in the circuit, inasmuch as the control was removed with the setting on neutral.

The var control functioned smoothly to maintain power factor of the circuit within the ability of the capacitor bank at point *C*. An average of about two

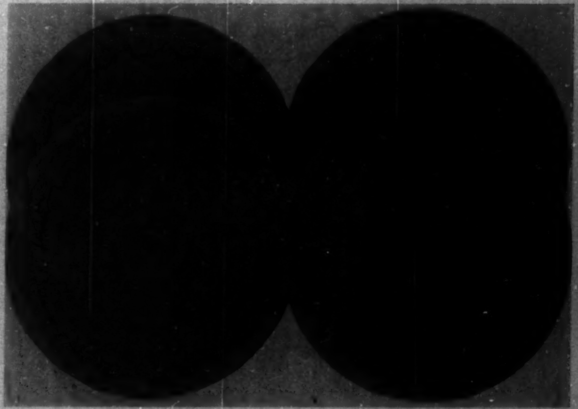
B—No line-drop compensation in regulation

C—No regulator in circuit

Fig. 7 (below). Voltage charts showing operations and results



operations per day resulted to a large extent from the switching of the voltage controls under different conditions.

Voltage control at the different points performed excellently after settings were made to obtain desired switching action between the various units. Noteworthy results were found, after proper adjustments, in obtaining selective operation of the separate units as result of varying loads delivered at different times at points *L*, *M*, and *N*.

Discussion

Bandwidth of a control setting must be large enough to avoid pumping from the operation of a bank under a given control. Occasional transfers from one control point to another developed as a useful operation in having the var supply actually in the area where it was needed. With compensation set in the regulator, bandwidth on voltage controls should be greater than the range of regulation at the point of control. In this case, capacitors will be switched after the regulator has reached its limit.

Capacitors can only raise the voltages level as they are applied, and their effect in this respect decreases as it is observed closer to the source than a first observation. When using capacitors for voltage improvement, the tap settings should take into account the highest voltage that may be encountered under the conditions that may develop.

The following generalities appear to be indicated:

1. Capacitors immediately after the regulator will improve the power factor of the load handled by the regulator but require modification of compensator settings.

2. Reactive control may be connected anywhere in so far as the regulator is concerned, but must be ahead of connections serving loads that should be considered.

3. Voltage control may be connected ahead of the regulator to control capacitors connected after that unit in the circuit.

4. Voltage control installed farther from the source than the regulator should be located beyond the point for which compensation is set, when possible. Excellent results were found with voltage controls after all compensation was removed from the regulator.

Unbalanced load between phases was found as a major problem when either voltage or var control was taken as the signal and obtained from only one phase. Improvement in voltage and power-factor balancing can be obtained:

1. By balancing load carefully between phases, which includes observation of the diversity of load on the different phases.

2. By using single-phase regulators to improve voltage balance only.

3. By using automatic control to switch single-phase capacitor banks along the laterals which produce the unbalance.

Conclusions

The results developed in these tests suggest several possibilities and demonstrate certain necessities if full advantage is taken of the new controls:

1. To achieve optimum benefits in such applications, it becomes apparent that adequate measurements are needed to determine conditions of load and voltage with the installation of comprehensive control of capacitor banks.

2. The combination of regulator and automatic control units can be used to produce a narrow bandwidth and a small spread in voltage over the length of a distribution feeder. This improvement in regulation together with control of power factor offers the possibility of maximum utilization of the thermal capabilities of the various elements of a given circuit.

3. A group of automatically controlled capacitor banks can be used to provide step-voltage control. Such units contribute their share to the benefit of generation and transmission systems also, at moderate costs, as compared with large station banks.

4. Automatic controls will generally remove the capacitors, or connect them, in proper arrangements to meet the unscheduled changes of a system or load which occasionally develop without warning.

Discussion

Clark Denison (Oklahoma Gas and Electric Company, Oklahoma City, Okla.): Our studies and experience confirm the authors' statements regarding locating capacitors as near as feasible to the var consuming loads and equipment. The economic factors have shown that in our case it is highly desirable to locate the greater part of these on distribution feeders with the switched capacitors controlled so as to correct power factor to as near unity as feasible. By the same reasoning, switched capacitors on substation busses, particularly when supplied by low-voltage subtransmission, are economically sound if they are sized to fit var needs in supply lines and substations only.

We have found time switch control a very useful low-cost method of achieving desired conditions on distribution feeders. This control method insures maximum correction during system peak load periods which determine our design and capacity limitations. We feel this consideration may outweigh local feeder conditions where reactive or voltage control may seem to be a better solution.

The tests made in connection with this paper demonstrate the superiority of thermally activated reactive and voltage controls over the older instantaneous controls. These older controls were subject to excessive operations due to temporary conditions and thus were not adaptable to co-ordination with narrow control bands and selective operation as are new thermal controls. Even with these narrow control bands the tests show in two of three trials that one of the switched capacitors was not switched off, indicating that a typical feeder could logically include unswitched capacitors to the extent of the light load var demand. The tests also indicate switching time of the var controlled capacitor might be predictable enough for substitution of time clock control near the feed point.

Our company has already begun a program of combination time clock and voltage controls on substation bus capacitors to insure use during peak loads and still have the capacitors available at other times for voltage improvement during emergency operating conditions. In cases where this improvement is insufficient or where bus capacitors do not exist, it appears logical that the same combination control could be justified on at least part of the individually switched capacitors on distribution feeders.

As in most utilities our new service areas in the outskirts of cities are being served from higher voltage subtransmission and tap-changing transformers supplying trunk-type 12.5-kv distribution feeders. These areas are ideally suited to relatively large switched capacitors which should logically have combination time clock and thermally activated voltage controls with no substation bus capacitors at all.

The use of time clock control during predictable peak load conditions rather than single-phase var control would avoid application troubles due to unbalanced loads at feed points inherent in 3-phase regulated feeders. With combination voltage controls on part of the feeder switched capacitors, time clock control periods could be limited to more predictable load periods, thus avoiding many situations such as week ends, changeable weather periods, etc. By the proper co-ordination of controls the installed capacitors can be made much more adaptable to system as well as local feeder needs with the new thermally activated control devices.

W. H. Cuttino (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Although automatically switched capacitors have been used on many distribution circuits for a number of years and their advantages in supplying the kilovars as needed to improve voltage conditions, release system capacity, and reduce system losses have been known, there has not been sufficient information published showing results on specific circuits. The information given by the authors should be quite interesting to the distribution engineers, particularly those embarking upon a program of adding switched capacitors.

When automatically switched capacitors are applied it is important that the bandwidth of the sensing device have sufficient spread to avoid "pumping." If several switched capacitors are applied on one distribution circuit the switching of one capacitor may affect the sensing signals at other capacitor locations. This is particularly true in the case of voltage-sensing devices and often occurs in the case of other sensing devices, depending upon their location in the circuit. The change in signal should be known at all switched capacitor locations when capacitors are switched at any one of the other locations to guard against the possibility of the capacitor switch pumping. It would be interesting to know what these values are for the circuit in the paper.

It is assumed that Mr. Fowler and Mr. Thomas do not necessarily propose using automatically switched capacitors at all locations shown in Fig. 1. It appears that one or two unswitched capacitor banks might be applied in the interest of economy with satisfactory results.

W. C. Fowler and C. W. Thomas: We appreciate the contributions made in the discussions which add to the value of the report of the tests. In connection with Mr. Denison's experienced comment on time switches, it might be mentioned that one of the banks that was automatically switched during the test period is to be operated in the future on a time schedule. However, the effectiveness in supplying vars as close as possible to the point of use is lost to a small degree in this change.

The paper gave complete results on three selected days to present typical results of various settings on "normal" days. During various "abnormal" days it was found that all banks were switched on at some times and all switched off at other times, but the conditions would not be predictable.

After the problem of unbalance was realized it was readily allowed for in setting the single-phase varmeter. The actual settings used were those found to accomplish the desired results by observing the polyphase graphic varmeter at the substation and the proportion of unbalance in reactive loads held sufficiently steady to make the operation very satisfactory. If the regulator had been in the substation it would have been convenient to measure and control the bank from polyphase measurements at that point, with a control circuit carried out to a suitable location for the switched bank.

In response to the question from Mr. Cuttino, the calculated effect of the last capacitor bank was 3 volts, which was exactly the amount observed on an instantaneous voltmeter. With compensation removed from the regulator, this unit acted to restore most of the effect of switching with the time delay of the regulator. The time delay of the thermal control was ample to allow the regulator to complete its function. The net effect found at the last bank of capacitors, after the regulator had returned to its set value, was slightly less than 3/4 volt. The effect was 1/2 volt at each of the other two banks under voltage control. Pumping did not occur until other settings were tried wherein the bandwidth on the voltage controls was reduced to a smaller value than the bandwidth on the regulator.

Mr. Cuttino suggests the merit of fixed banks in securing results at the least expense. A decision on this feature has been delayed pending minimum values of reactive load during the season of lightest loads. It appears that even 300 kilovars would be too much for the circuit to satisfy system requirements at such times. This feature of capacitor applications also identifies itself with the possible use of secondary capacitors at appropriate points where they may justify themselves. The switched capacitors should serve the purpose of handling the variations in reactive load above the minimum values.

An Analogue Solution of Cable Heat Flow Problems

E. de HAAS
NONMEMBER AIEE

P. J. SANDIFORD
NONMEMBER AIEE

A. W. W. CAMERON
MEMBER AIEE

Synopsis: Steady-state heat flow problems related to buried cables can be solved with a simple electric analogue. The soil is represented by graphite-coated paper, and the cables and sinks by fixed electrodes applied with silver paint or by movable copper cylinders. Regions with lower thermal resistivity (t/r) than the main soil body (duct banks, special backfill) are simulated by placing one or more extra sheets of graphite paper on the base paper in electric contact with it. Applications described include a duct bank problem and a double-circuit pipe-type cable placed in a rectangular box of sand. The load reduction caused by close spacing, the beneficial effect of sand backfill in poor soil, and the influence of ground water are discussed.

EQUATIONS for the heat flow from an underground cable or a group of cables have been given by Neher.[1,2] His solution is based on the Kennelly equation and works satisfactorily for various configurations. Fink[3] has applied it to cases where special backfill is used to bring the over-all thermal resistivity of an otherwise poorly conducting soil down to a more suitable design value. Exact calculation is difficult or impossible in a number of practical cases, e.g., when twin circuits are placed in a rectangular box of backfill. An electric analogue, assembled with simple equipment, may then supply steady-state solutions of sufficient accuracy.

Principle

Heat flow from a system of n parallel buried cables is basically a 2-dimensional problem in a plane perpendicular to the direction of the cables. When a steady state has been reached, the temperature satisfies Laplace's equation, and it may be written

$$\Delta T = T_n - T_A = R_{nA} W_n$$

where

T_n = surface temperature of cable n in a system of cables
T_A = temperature of a sink A
R_{nA} = thermal resistance between n and A per unit length of cable
W_n = heat transported from n to A per unit of time and per unit length of cable
ΔT = temperature rise above ambient

The same law holds for an electric flow where current is transported from a number of sources to a number of sinks

Paper 55-55, recommended by the AIEE Insulated Conductors Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 22, 1954; made available for printing December 6, 1954.

E. de Haas, P. J. Sandiford, and A. W. W. Cameron are with the Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada.

The authors wish to acknowledge the stimulating discussions of these problems with colleagues at Ontario Hydro and with the other members of the AIEE Task Group on Study of Soil Thermal Resistivity, at whose request this paper is presented.

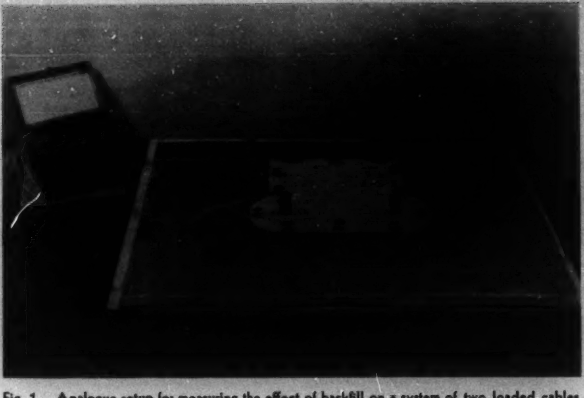

Fig. 1. Analogue setup for measuring the effect of backfill on a system of two loaded cables. The weights serve to keep the extra paper in contact with the base sheet

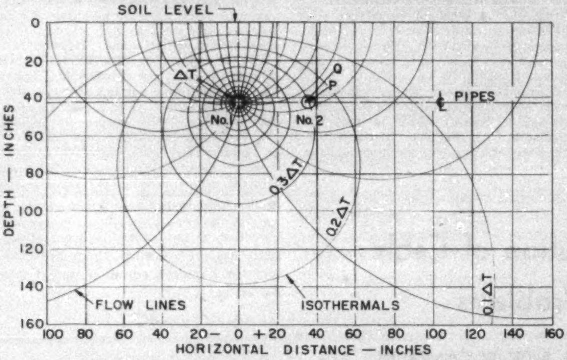

Fig. 2. Kennelly diagram of one loaded pipe. The second pipe is centered on the 0.3ΔT isothermal

$$V_n - V_A = S_{nA} I_n$$

where

$V_n - V_A$ = potential difference between n and A
S_{nA} = electrical resistance between n and A
I_n = current from n to A

The advantage of studying heat flow with an electric analogue lies in the fact that the electrical quantities reach their final (steady-state) values immediately. Besides that they are much easier to measure. Afterwards the solution is again translated into terms of heat.

Experimental Arrangement

A modification of a commercial analogue field plotter was very well suited for this model study. It uses a paper coated with a uniform layer of graphite, which is available in two varieties with approximately 10,000 and 1,000 ohms of surface resistivity. It has been found that the low-resistivity paper is best adapted for the purpose.

Desired combinations of electrodes are applied conveniently by covering the affected regions with silver paint and using fast-drying butyl-acetate as a thinner. Because the problem requires only quantitative values of the thermal resistances, there is generally no need to plot the actual field lines in the model study. It is sufficient to measure the electrical resistances with an ohmmeter or to calculate them from current and voltage; see Fig. 1.

Experimental Proof for the Validity of the Method

A simple system with well-known characteristics was set up on the board. It consisted of two circular electrodes and one straight bar, representing two cables buried below the surface of the soil; see Fig. 2. Assume that at first only one cable is loaded and dissipates heat at the constant rate of W watts per centimeter (cm), which keeps the outer diameter of the cable at ΔT degrees above the ambient. The isothermals marked $0.1\Delta T$, $0.2\Delta T$, etc., show the distribution of the intermediate temperatures. Pipe no. 2, similar to pipe no. 1 but not heated, placed at P, will attain the temperature prevalent at this point, i.e., $T_A + 0.3\Delta T$. When pipe no. 2 also becomes a heat source dissipating W watts per cm, superposition of the two heat-flow fields will raise the temperature of no. 2 to $T_A + 0.3\Delta T + \Delta T$, or $1.3\Delta T$ above the ambient (sink). The same applies to no. 1 as it is lying on the $0.3\Delta T$ isotherm of no. 2. This means in effect that the presence at this distance of a second loaded pipe increases the temperature of pipe no. 1 by 30 per cent for an unchanged dissipation from no. 1. In other words it raises the thermal resistance between no. 1 and the surface by a factor 1.30.

If the analogue method is correct, the same ratio should apply to the electrical resistances. This was investigated. The result was a measured ratio between the electrical resistances $S^*/S = 1.32 \pm 0.01$ compared with the theoretical value of 1.30, where

S = resistance from no. 1 or no. 2 to A when only one pipe is dissipating heat W
S^* = resistance from no. 1 or no. 2 to A when both pipes dissipate W

The error is principally caused by the fact that the introduction of a conducting disk at P disturbs the original field distribution around pipe no. 1.

It is conceivable that the left side of the disk 2 which is closest to pipe no. 1 is more active in increasing the effective resistance between A and no. 1 than the right side. In other words, the center of gravity of the influence of the disk is not

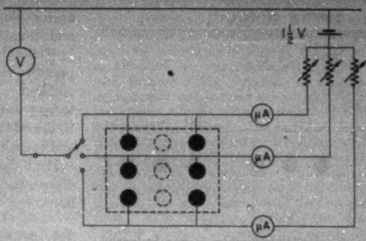

Fig. 4 (right). Electrical diagram. Current return path through graphite paper is not shown. The rheostats are adjusted until the microammeters show equal current. The resistances are calculated from voltage and current readings. If desired, the microammeter can be adjusted to unequal currents, corresponding to uneven loads

P but a point *Q*, closer to pipe no. 1. For example, if *Q* were located as in Fig. 2, the theoretical ratio would be 1.32. This type of discrepancy between theory and experiment would, however, also occur in the case of buried pipe-type cables and does, therefore, not affect the applicability of the method for solving practical problems. Consequently, the error in the use of the analogue is not above 2 to 3 per cent, which is permissible for the solution of cable heat-flow problems. At the same time it was found that edge effects are negligible when the sheet of paper is at least three times as long and three times as wide as the model.

Inhomogeneous Soil

For installations in inhomogeneous soil, the analogue should provide for paper with correspondingly varying resistivity. This is also the case if the cables are in ducts or if there is special backfill.

Although an analogue using an electrolytic tank of adjustable depths would normally be used for problems of this type,[4] the paper technique had proved so convenient for the homogeneous case that it was undertaken to modify it for use in backfill problems. Thus one or more extra sheets of graphite paper were placed on the base sheet, reducing the local resistivity to one-half, one-third, etc., of its original value. To get good contact between the sheets without disturbing the flow pattern unduly, the edges were dotted sparingly with silver paint before the sheets were laid in place.

Applications

CABLES IN DUCT

When plans were being considered for two 115-kv 125-megavolt-ampere (mva) circuits in the Toronto area, one proposal was to place the six single phases in a duct bank, as shown in Fig. 3. In such cases it is usual to apply the National Electronic Light Association (NELA) equation when calculating the current rating of the cables. The NELA equation is based on an average t/r value and does not take into account the local t/r of the soil around the duct, which in the case under consideration was 120 degrees centigrade (C) cm per watt. The concrete t/r was 100 C cm per watt. Application of Neher's equation, which does allow for high soil t/r values, would restrict the cable rating to 100 mva per circuit, where NELA permitted 125 mva. Because of this appreciable difference in capacity resulting from the two calculating methods, the analogue was used to determine which equation was suitable. A model was made with single and double extra sheets representing the duct. Resistances were measured between each cable and the sink with all cables carrying full and equal load; see Fig. 4.

If the base sheet represents a resistivity of 120 C cm per watt, the duct portion consisting of a base sheet plus one extra sheet corresponds to 60 C cm per watt, and with two extra sheets to 40 C cm per watt. As in reality the t/r value of the duct was 100 C cm per watt, the corresponding resistance values were found by interpolation. Table I gives the analogue results and the values computed from the two equations. The good agreement between the Neher values and the analogue values is evident.

EFFECT OF BACKFILL

In a case of a route for two pipe-type cables with localized areas of high t/r, up to 300 C cm per watt, the question arose whether sand backfill extending to 2 feet above cable level would be adequate; see Fig. 5. The Kennelly equation gave for one cable buried in homogeneous soil with a thermal resistivity ρ C cm per watt

$$R=0.48\rho$$

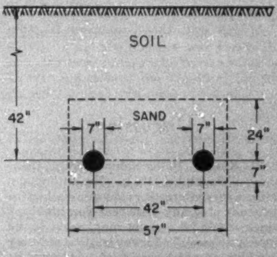

Fig. 5. Two loaded pipes in a rectangular box of sand

Table II. Thermal Resistance Between One Cable and Sink in Thermal Ohms for 1 Cm of Cable

Soil t/r, C Cm per Watt	Without Sand		With Sand 2 Feet Above Cable Level		With Sand Filling Whole Trench	
	R, One Cable Only	R′, Second Cable Loaded Also	R″/R′ Per Cent	R″	R‴/R′ Per Cent	R‴
80	38	49	100	49	100	49
160	77	98	82	80	69	68
240	115	147	68	100	48	71
320	154	196	58	114	37	73

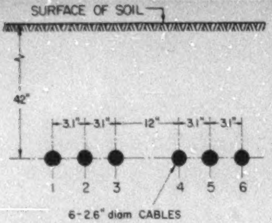

Fig. 6. Six loaded cables in one horizontal plane

where

R = thermal resistance in thermal ohms per cm length between the sheath of the cables and the sink when no other loaded cable is present

The presence of a second cable at the given distance brings R up to

$R' = 1.28R = 0.61\rho$

where

R' = as in the foregoing but with the second cable loaded to the same level as the first one

R'' = as in the foregoing but with both cables surrounded by sand, as indicated in Fig. 5

To evaluate the beneficial effect of the sand ($\rho = 80$ C cm per watt), a model was made and extra sheets of paper corresponding to the sand were placed on the base sheet. One extra sheet corresponded to sand with $\rho = 80$ surrounded with soil of $\rho = 160$; two sheets to sand $\rho = 80$ surrounded with soil $\rho = 240$, etc. Thus it was possible by a series of tests to measure the ratio R''/R in soils of various t/r. The results are given in Table II.

During the investigation it was tried out how much improvement could be obtained by filling the trench with special backfill right to the surface. The difference is apparent in poor soil where the sand acts as a short circuit for the heat flow. See Table II, where R''' represents the resistance to sink in a wholly sand-filled trench.

At full load the dissipation W from each cable amounted to 1.0 watt per cm and, thus, the figures for R, R', and R'', in Table II directly represent the temperature rise of the cable sheath over the ambient. Taking into account that the temperature of the sink may be as high as 25 C and that the rise between conductor and sheath at full load is also 25 C, it is evident that under normal full load conditions the conductor might become too hot.

Six Cables in One Plane

When the installation mentioned in the section entitled "Cables in Duct" was under consideration, the suggestion was made that the six phases be directly buried, as shown in Fig. 6. A model study was made to determine the thermal effect of close spacing.

If the thermal resistance between one single phase—no other phases loaded—and the surface of the soil is standardized at 1 thermal ohm, the resistances for all cables loaded were found between:

cable 1 or 6 and sink:	3.6 thermal ohms
cable 2 or 5	: 3.8 thermal ohms
cable 3 or 4	: 3.8 thermal ohms

From these figures it could be computed that the load-carrying capacity of phases 2, 3, 4, and 5 was only 54 per cent of the full capacity, available when the six conductors were spaced without overlapping heat-flow paths. In other words, the six cables in the given configuration do the work that four conductors of the same size could do if they were spaced sufficiently widely.

These derating factors could also have been computed from the Kennelly equation by superposing the six heat fields. An advantage of the analogue was the use of adjustable electrodes consisting of short copper cylinders mounted on adjustable arms with a small drop of mercury trapped between each electrode and the paper for good contact. In this way it was possible to observe the effects of various spacings and groupings on the resistance. This otherwise would have required many repetitions of the calculation.

Table III. Effect of Ground Water on Thermal Resistance

Heat Sink	Resistance in Thermal Ohms Between Cable and Heat Sink		
	Cable 1 or 6	Cable 2 or 5	Cable 3 or 4
Earth's surface	3.6	3.8	3.8
Earth's surface plus ground water	2.8	2.9	2.9

Effect of Ground Water

It is often observed that the actual temperature attained by the pipe of a buried-pipe-type cable is less than the value computed from the observed thermal constants of the soil and cable, using the Kennelly equation. It has been suggested that this may be caused by the ground water which may be as effective a heat sink as the surface of the earth.

To test this on the analogue another electrode was painted on the paper parallel to the one representing the earth's surface at a distance corresponding to 118-inch depth (about 10 feet of water table). It was connected electrically to the "earth's surface" electrode, thus corresponding to ground water at the same temperature as the earth's surface. The results are shown in Table III. Similar tests for other configurations show that such an additional heat sink is very effective in reducing the thermal resistance with a corresponding increase in the cable rating. Whether or not the ground water acts in this manner must, of course be determined by field tests.

◆

Discussion

A. H. Kidder (Philadelphia Electric Company, Philadelphia, Pa.): The authors describe a very interesting analogue method for the study of steady-state heat-flow problems which should be a useful supplement to the previously published investigations of Neher and Fink, to which they refer. It should be noted, however, that the method deals exclusively with steady-state rather than transient temperatures. The graphite-coated paper used for constructing their electrical analogy of the steady-state heat flow accurately represents a homogeneous environment. The suggested superposition of the sheets permits a corresponding increase of electrical conductivity when desired to represent approximately the use of some special back-fill, and accordingly modifies certain boundary conditions which would be difficult to evaluate mathematically. The basic principle, however, is that of steady-state heat flow in homogeneous media. The analogy is of course incapable of representing transient effects of variable cable loading, because the distributed capacity effects are not accounted for.

I am quite disturbed, therefore, by the authors' reference to the effect of ground water as an additional heat sink which they seem to think is needed to explain the fact that the actual temperature attained by a buried cable is found to be less than the steady-state value which can be computed by appropriate use of the Kennelly equation. The most likely explanation of the lower temperature attained is that the cable loads are far from constant for the great length of time necessary to achieve the steady-state temperature distribution which the Kennelly formula (see reference 1 of the paper) and their analogue are designed to represent. For ground water to be a heat sink, it must be moving so as to carry the heat away. When the improbability is considered of ground-water flow in sufficient volume to become a heat-sink, it is recognized that the only heat sink which can be counted upon is that of the atmosphere above the surface of the earth, the surface temperature distribution of which would also be modified by the presence of the buried heat source.

When Mr. Neher and I were first confronted with this problem of heat dissipation in earth several years ago, we were handicapped for some time by the generally prevalent but fallacious notion that the so-called deep-isothermal was a heat sink. I have no doubt that the authors' painting another electrode on their graphite-coated paper probably served the purpose of reconciling the analogue readings with an observed cable temperature in some situation. However, this artifice should be understood to represent nothing more than a purely empirical conclusion introduced to compensate for factors not accounted for in their attempted steady-state representation of transient phenomena.

W. A. Sinclair (The Detroit Edison Company, Detroit, Mich.): This excellent paper furnishes us with another tool for solving heat flow problems. Load reduction due to close spacing, the beneficial effect of sand backfill in poor soil, and the influence of ground water are particularly important to those of us concerned with the operation of cable systems.

The application of the analogue to the cables in duct was very interesting. At Detroit Edison we have considered the soil thermal resistivity inherent in the NELA heating constants to be 70 watt-cm units. If the results shown in Table I for the NELA equation had been corrected for the higher value of resistivity, the resultant values should check reasonably well with those given for the Neher equation or the analogue.

The second application of the analogue to the effect of backfill was extremely interesting. At Detroit Edison we have encountered areas of high thermal resistivity up to 200 C cm per watt along the route of one of our 120-kv pipe cable lines. The standard backfill called for 6 inches of yellow bank sand around the pipe. Through a portion of the area in which high thermal resistivity soil was encountered, 1 foot of yellow bank sand around the pipe was used in place of the customary 6 inches. Through the remainder of the high-resistivity area, the elevation of the pipe was lowered 1 foot which brought it nearer to the ground water level. This was an attempt to take advantage of ground water as a heat sink as described by the authors in the fourth application of the analogue. It will be interesting to see how the pipe-operating temperatures through this area compare with those obtained on the balance of the line.

Fig. 4 shows the pipes with 4 inches of sand at the sides and $3^1/_2$ inches below them. It has been common practice to surround the pipe with at least 6 inches of sand for single-pipe installations. In addition we have also filled the trench to the surface on some installations with yellow bank sand. Fig. 1 indicates that the amount of backfill adjacent to the sides and bottom of the pipe would have an important part in determining the thermal resistance of the earth path. It would be helpful if the authors could give us some data in which they considered greater amounts of sand adjacent to the sides and bottom of the pipes than were used for the effect of backfill. This could be a very important area since approximately 50 per cent of the thermal gradient horizontally out from the pipe occurs in the first 6 inches of the earth.

L. H. Fink (Philadelphia Electric Company, Philadelphia, Pa.): The application of the analogue field plotter provides a convenient means for the solution of certain cable heat flow problems which are not suited for the usual mathematical solution based on the Kennelly equation. Such a problem, for instance, is presented when the trench in which a cable system is buried is backfilled with a material of thermal resistivity differing appreciably from that of the surrounding soil. The mathematical difficulty is caused by the fact that since the contour of the backfill material does not conform to the natural isothermal lines to be found in a homogeneous region, the heat field and the flow of heat become distorted, making their mathematical description complicated and impractical. The same sort of difficulty, of course, is encountered in the solution of duct bank problems, but usually the thermal conductivity of the concrete duct bank is close enough to that of the surrounding soil for the difference to be ignored. In any case, it appears that all such problems can now be solved readily and with satisfactory accuracy by the analogue plotter. At the same time, there are cases in which the mathematical approach is still the more convenient. For instance, in the case of severe moisture migration, the resistivity of the soil may perhaps be found to vary inversely with distance from the pipe. Such a continuous variation in resistivity would be difficult to reproduce on the plotter, but Neher (see reference 1 of the paper) has shown how it may be handled readily by equation.

Despite the differences in applicability of the two methods of solution, Kennelly equation and analogue field plotter, they are basically the same, being based on the same thermal-electrical analogy. In the simple case of a uniform soil, where both are equally applicable, their respective results should check closely, and this is seen to be the case in Table I. However, because of this very fact, that the two approaches are fundamentally the same, concurrence of their results is to be expected, and neither approach can be cited as justifying the other or showing its validity.

Another consequence of this underlying identity is that certain idealizing assumptions are common to both. One such assumption is that the surface of the earth is an isothermal, having in effect perfect surface conductivity. Neher (see reference 1 of the paper) has shown that in the usual case, with an undistorted heat field, this assumption is sufficiently close to the fact as to introduce no appreciable error. However, because of the versatility of the analogue device, the authors have been able to treat a case where the error may exceed that computed by Neher. This is the example where the trench is filled to the surface with corrective backfill. As the authors observe, this provides a complete, low-resistance path between the heat source and the ground surface, through which most of the heat will flow. This concentration of heat flow directly above the source may cause the drop due to the surface resistance of the soil to be much greater at that point than at a short distance to either side. Since the analogue plotter, as described in the paper, always maintains an isothermal for the earth surface, its results in this extreme case may not be as valid as in other cases. Perhaps a substance of higher electrical resistivity could be used to simulate the ground surface.

The use of a second ground bar to simulate the effect of a water table acting as a heat sink is interesting. Such an approach would seem justifiable in cases involving a subterranean flow of water carrying off the heat by convection; whether it is permissible in other cases deserves further consideration, especially since, in dealing as we are with steady-state solutions, the thermal capacitance of the water should not be involved.

Finally, a very useful application of the device has been suggested by one of the authors. In reference 3 of the paper a set of curves was presented to show the dimensions of a trench which, when backfilled with material of a given thermal conductivity, would achieve a desired amount of improvement in over-all effective soil conductivity. Being based on the mathematical solution, difficulties of which are outlined in the foregoing, these curves represent trench dimensions conforming at least approximately to the isothermals of the undisturbed heat field and, while valid, they do not represent the most economical solution possible, either with regard to volume of backfill required or to required depth of excavation. The analogue field plotter makes it possible to determine trench dimensions which will result in greater economy of labor and material while providing a given degree of reduction in effective thermal resistance. A series of curves giving such dimensions for typical conditions would be of real value.

In demonstrating the facility and effectiveness with which the analogue field plotter can be applied to cable heat flow problems, the authors have performed a valuable service, and deserve the thanks of the engineers who deal with these problems.

F. H. Buller (General Electric Company, Schenectady, N. Y.): The authors have performed two services in presenting this paper; first, they have demonstrated clearly with examples how difficult heat flow problems, encountered in connection with buried cables, can readily be solved by the proper use of an inexpensive commercial device; and second, they have drawn attention to a device which has many other obvious applications in the study of heat-flow problems,

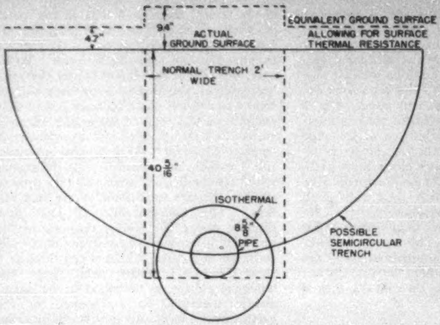

Fig. 7. Buried pipe cable, showing one isothermal and some possible trench arrangements

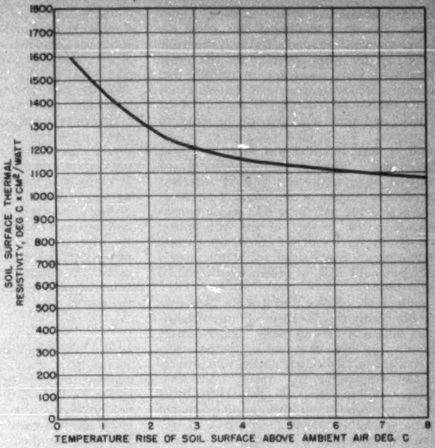

Fig. 8. Surface thermal resistivity of soil based on 32 C ambient air, wind velocity neglected

electrostatic and electromagnetic field problems, etc. It is clear that analogue computers of this character have potentially a wide application in cable practice.

A particularly valuable feature of their approach is the possibility of a detailed study of the effect of environmental modifications in improving buried cable performance. In his discussion Dr. Wiseman has stated that where soil thermal resistivity is excessive it should be reduced to a value of 80 or better by means of such modifications. Schiffreen has pointed out that environmental modifications, while helpful from the standpoint of cable rating, can be very costly. This raises the question as to how far one should go in modifying cable environment and exactly what form the modification should take for best results.

For example, a heat field can be plotted and the material between two adjacent isothermals can be replaced with some other material of, say, half the thermal resistivity of the remainder of the soil. This can be done, for instance, in the case where the "cable" is a pipe of $8^5/_8$-inch outside diameter buried at a depth of 3 feet, and the isothermal in question is the one whose highest point is at a depth of $27^3/_8$ inches below the surface of the ground (see Fig. 7). In this case, a reduction of about 16 per cent in soil thermal resistance may be expected if the soil is homogeneous and the surface thermal resistivity of the soil is negligible.

On the other hand, if a semicircular trench is excavated with its lowest point passing through the pipe center and this trench is backfilled with material having half the thermal resistivity of the surrounding soil, the thermal resistance of the system may be reduced by as much as one third, or $33^1/_3$ per cent.

These results are obtained from rather simple mathematical analyses of the problem. It may not be practical, however, to dig a trench 6 feet wide or to dig cylindrical trenches to match the isothermals of the heat field; nor are these solutions necessarily the best from the economic standpoint. Other solutions, such as backfilling a 2-foot trench with soil of low thermal resistivity, may lead to very difficult mathematical problems, perhaps necessitating important and possibly inexact approximations or, alternatively, tedious and costly numerical analyses in order to get an answer. Such solutions, however, can be very simply and inexpensively obtained with an analogue device such as that used by the authors; several possible solutions can in fact be prepared easily, cheaply, and expeditiously, and the best one selected for actual use.

A question has been raised about the effect of the soil surface thermal resistivity on the validity of these studies. This effect is in general rather slight; with a soil surface thermal resistivity of 1,200 and a soil thermal resistivity of 100, the temperature rise of the pipe mentioned would be increased only about 4 per cent by the effect of surface thermal resistivity. This increment increases as the soil thermal resistivity decreases being about 8 per cent for a soil thermal resistivity of 50.

If the soil is homogeneous and if its surface thermal resistivity is uniform along the entire surface of the soil, a very simple equation is available for evaluating the effect of soil surface thermal resistivity. The effective depth of burial becomes

$$D_{eff} = D + \rho_s/2.54\ \rho_e$$

In this equation, D_{eff} is the effective depth of burial to be used in the Kennelly equation or its variations, in inches; D is the actual depth of burial in inches; ρ_s is the thermal resistivity of the surface of the soil, and ρ_e is the thermal resistivity of the soil in the usual watt cm units. This makes the problem very easy to handle on the analogue computer.

If the pipe is installed at a 3-foot depth and the width of the trench is 2 feet and, further, if the thermal resistivity of the soil is 100 while that of the backfill is 50, and if the surface thermal resistivity of the soil is 1,200, a reasonably good approximation may be obtained on the analogue computer by placing the surface of the soil at a distance of 9.4 inches above the true depth of burial across the width of the trench, and at a distance of 4.7 inches above the true depth of burial for the rest of the soil. Such a surface discontinuity, of course, implies an approximation if the Kennelly equation is used; however, since we are dealing with a rather small correction, the approximation should be a good one.

To simplify the application of the foregoing equation, Fig. 8 has been prepared, giving the calculated value of the surface thermal resistivity of the soil for an air ambient of 32 C and on the assumption of a negligible wind velocity. A change in the air ambient will change these values only slightly, a reduction in the air ambient resulting in an increase in the surface thermal resistivity; if an appreciable wind is present there will be a tendency to reduce to some extent the surface thermal resistivity of the soil. The maximum surface rise (directly over the pipe) will usually be of the order of 3 to 5 C. It is evident from this curve that a surface thermal resistivity value of 1,200 to 1,300 is fairly representative of the surface conditions which will actually be encountered, and that the assumption of a uniform surface thermal resistivity is a reasonable one in view of the small magnitude of the correction involved.

R. J. Wiseman (The Okonite Company, Passaic, N. J.): The paper should be given consideration by engineers who are interested in the dissipation of heat from buried cable systems. Although we assume that the Kennelly equation represents the heat flow from a buried cable, some of us are none too sure that it is correct, in that the measured thermal resistivity of the soil must be modified in order to check measured cable temperatures. This analogue provides a means for a comparison of calculated and measured resistances.

I like very much the section on applications and their findings. What is needed is a comparison of the calculated values of thermal resistance of the various setups and the values found by the authors. Do they check each other's findings or is there a difference that might result in a correction factor for the calculated value? For example, in the subsection "Effect of Backfill," the authors state that the Kennelly equation gives for one cable buried in homogeneous soil a resistance of $R = 0.48\ \rho$. Is this by calculation? If so, what was found by the analogue? If the same value was obtained, then we can have more confidence in the Kennelly equation. If not, what is the correction factor to be used in the log equation to obtain the same value? How does this correction factor compare with the correction factor now used in the log equation? It has been customary in the past to assume a value of thermal resistivity ρ of 180 thermal ohm cm, but we take a value of $2/3\ \rho =$ 120 thermal ohm cm in the log equation. This is still not correct, so values of effective thermal resistivity are taken over the range of $\rho = 80$ to 100 thermal ohm cm, or (0.45 to 0.56) ρ. Is the error due to the equation or to incorrectly measuring the soil thermal resistivity?

In Table I the authors compare the thermal resistance between cable and soil surface for a duct installation. For the Neher equation and the analogue they check very well, but using the NELA duct-heating constants, the thermal resistance is very much lower; in fact, the ratio of the analogue to NELA is 1.58 for the top duct and 1.68 for the center and bottom ducts. The authors are bringing out the fallacy in the duct-heating constants. When these were first set up, they served their purpose very nicely, but since buried cable systems have become of interest, and comparison is made with a duct system, we find that a cable in a duct system, using the NELA heating constants, will carry a greater load than one directly buried. This is because in the case of the duct heating constants, they are set up for various numbers of cables in the duct bank, but do not differentiate among the several possible geometric arrangements of the ducts, the number of active ducts (yet there may be many idle ducts), the depth of burial, and the soil thermal resistivity. It would appear that the authors have taken the duct constant for 6 cables in a duct bank, namely, $6 \times 0.82 = 4.92$ thermal ohms per foot (150 thermal ohms per cm), and for the analogue they use a value of 120 thermal ohm cm for the earth around the duct bank. In Fig. 3 they give the configuration of the duct bank. From it, it is possible to compute the thermal resistance of the duct bank and surroundings, assuming the Kennelly equation to be correct. If it is assumed that 4.92 thermal ohms per foot is correct as per duct-heating constants, this is equivalent to a soil thermal resistivity of about 65 thermal ohm cm. Now, if we take a value of 120 thermal ohm cm in the same equation, we get a value of 8.18 thermal ohms per foot (250 thermal ohms per cm) or a ratio of 1.66 between the two soil conditions, which compares with the ratio of 1.68 obtained by the authors. This shows that it is not correct to use the present duct-heating constants if a comparison is to be made with a buried cable where the latter has a soil surrounding it with a thermal resistivity higher than 65 to 70 thermal ohm cm. To overcome it, we should use the Neher method for obtaining the duct thermal resistance. I hope that some day we will be able to revise the present duct-heating constants based on the Neher method. We are indebted to the authors for showing us that the Neher method does give more accurate values of thermal resistance.

William A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): Paper rendered semiconducting by means of graphite or carbon black, has been used for obtaining analogue solutions of electric field problems. In such work errors were found resulting from uneven conductivity of the paper. These were eliminated by testing the paper with voltage applied so as to give equipotential lines, which on uniform paper would give some regular geometric pattern, such as a circle. Sheets which gave distorted patterns were rejected. It would be interesting to know if the authors made any such tests.

When a problem of cable ampacity (i.e., current-carrying capacity) is stated, it is usual to give a certain "ambient temperature" as a starting point.

According to Kennelly's equation, this temperature should be that of the ground at its surface. However, no one lays a thermometer on the ground for this purpose and the given ambient temperature is either that of the air or the ground at cable depth when the cable carries no load.

If the given ambient is that of the air, the thermal resistance from ground to ambient air should be included in the calculation.

If the given ambient is that of the earth at cable depth, it may differ from that at the surface, and presumably it would affect the heat flow from the cable. An extreme case may be imagined where the cable and ambient temperatures are equal but the ground surface much cooler. In that case the cable will have lower ampacity than indicated by the Kennelly equation.

The method used by the authors seems to be adaptable to ascertaining the errors introduced by these two interpretations of ambient temperature, and it is to be hoped that work will be continued along these lines.

R. W. Atkinson (General Cable Corporation, Bayonne, N. J.): The methods and materials used by the authors are well adapted to the solution of thermal flow problems. I have reported a large number of data by a similar method aimed primarily at electrical properties, particularly electrical stress.[1,2] For such a purpose, the materials used by these authors would probably present a problem because of lack of complete uniformity in resistivity. It is to be supposed, however, that the graphite-coated paper is completely adequate for the thermal analogue since gradients are not of direct consequence.

In their analysis the authors have treated the earth surface as an isothermal. To do this is not entirely correct as it may be observed where loaded cable circuits pass under a snow covered area. The snow is promptly melted in the area above the cables in weather which leaves the snow in place elsewhere. The method used by the authors may, fairly readily, be modified to take into account the gradient at the earth's surface and to allow for it.

The authors have made measurements to determine the effect on thermal resistance of a buried cable system if there is a "thermal sink," an isothermal surface below the cables unaffected in temperature by the heat from the cable system. The authors have not taken a position in advocacy of the theory but have merely evaluated it. My criticism of the theory is thus not a criticism of this paper. The isothermal surface below the surface remains isothermal only if it is not significantly affected by the heat flowing into and through it. It is very easy to conclude from temperature measurements made on loaded underground cables that there is such a sink because the enormous thermal storage capacity will introduce a time lag of weeks into the system. For measurements made in shorter time than this, the behavior will be as though there were such a "sink" as has been postulated. It seems likely to me that most of the experimental basis for the "sink" theory has resulted from this fact. It seems desirable to point out, however, that the method of these authors can also be used, with slight additions, to investigate the ultimate equilibrium point that will be reached when all of the thermal transfer is by conduction. However, to determine whether movement of underground water may be a significant factor would seem to require actual measurements made with buried heat sources and temperature measurements.

E. de Haas, P. J. Sandiford, and A. W. W. Cameron: We are pleased that the paper has stimulated so much discussion on this timely subject.

We believe that the Kennelly equation is fundamentally exact, because it has been derived analytically from the basic Laplace equation for heat flow. The reason for some of the difference of opinion, as Mr. Kidder remarked, may be that the steady state is not reached for a considerable time after the cable has been loaded. Indeed, the very last portion of the temperature rise may occur only after some months from the initial loading.

We agree with Mr. Sinclair that the verification afterwards of temperatures on buried cables in correlation with the load would be very instructive. We plan to extend the model studies to larger amounts of backfill around the pipes or cables.

Mr. Fink mentions backfill economy. We have been trying to find the solution to the problem discussed in his paper[1] about the right amount of backfill to be placed around cables, but through a shortage of technical help we have not had a chance to do so.

Mr. Fink's remark regarding the surface resistance of the soil is best answered by Mr. Buller's discussion. We wish to thank the latter for his suggestions, which will make the analogue method more accurate in the case of extra backfill.

In answering Dr. Wiseman, we would say that the model studies cannot prove the truth of the Kennelly equation. As Mr. Fink remarks, the model applies the equation to more involved problems than can be solved analytically. We agree with Dr. Wiseman that the accepted present thermal resistivity values result in cables running much below the design temperature.

We thank Mr. Del Mar for his suggestion on testing the uniformity of the paper. So far, our tests have shown that the errors are smaller than 3 per cent.

The ambient temperature should be the annual maximum temperature of the ground at cable depth when the cable carries no load.

It is true, as several discussers have remarked that the NELA equation can give proper results, but this applies at only one thermal resistivity value, namely about 65 thermal ohm cm.

Mr. Kidder and Mr. Atkinson touch on the subject of heat sinks other than the surface of the soil. In the paper we have mentioned only that an analogue study can be used to evaluate the effect of such heat sinks, in case they exist. At present we think that there are not enough factors known one way or the other to enable us to discuss this point. However, the matter is well worth further theoretical and experimental study. Some field work is planned along a cable route close to Lake Ontario, where chances are good that the water table is only a few feet below the level of the cable. Geological observations have shown that in some cases the water can run perpendicularly to the cable with a speed of a few feet per day. In this case it would contribute significantly to heat removal.

In continuance of our program of model studies we have made a comparison between the observed values in the 6-cable problem (the third application in the paper) and a theoretical study, based on the principle of superposition. Agreement to within 3 per cent was reached.

Transfer of Steam-Electric Generating-Station Auxiliary Busses

D. G. LEWIS
ASSOCIATE MEMBER AIEE

W. D. MARSH
ASSOCIATE MEMBER AIEE

IN RECENT years there has been increased interest in methods of transferring steam-station auxiliary busses between normal and emergency sources. The problem has become more critical with increasing unit generator size and advancing steam conditions because of the larger motors which have slower voltage-decay characteristics and the larger auxiliary systems which generally tend toward poorer voltage regulation under bus-transfer conditions. There have been several published reports of tests made which show how voltages, currents, and speeds may vary during transfer on specific systems.[1,2] It is the purpose of this paper to discuss more generally the various kinds of bus transfer and to present a method by which it is possible to predict approximately the performance of a system under interrupted-circuit transfer conditions.

Kinds of Bus Transfers

Bus-Transfer Conditions

The large majority of modern generating stations are designed on the unit system, with two auxiliary power sources. Usually the normal source is associated with the main generating, unit as a transformer connected to the generator leads, or a main shaft-driven auxiliary generator. The second source is usually from the system, and provides power for starting up as well as for emergency conditions. It is necessary, then, to recognize two kinds of transfer between these sources: the routine transfer, made when the generating unit is started up or shutdown; and the emergency transfer, made upon failure of the normal source to provide power at adequate voltage. These two kinds of transfer have different requirements and, frequently different methods are used.

Method of Bus Transfer

Three methods of transfer may be used, characterized by the sequence and timing of operation of the source circuit breakers:

1. Continuous-circuit or paralleled transfer.
2. Interrupted-circuit transfer where there is no intentional delay between tripping the primary source circuit breaker and closing the secondary source breaker.
3. Interrupted-circuit transfer where the closing of the secondary source breaker is deliberately delayed after the primary source breaker is tripped.

Criteria for Successful Bus Transfer

The criteria for successful bus transfer are:

1. That no component of the auxiliary system shall be subjected unnecessarily to excessive duty as a result of the transfer.
2. That the performance of the auxiliary system shall be such as to permit continuous output of the main generating unit or to maintain adequate control for safe shutdown.

The most critical equipment under the first criterion is the motors which may be severely stressed by high inrush currents which can result from a nondelayed interrupted-circuit transfer. This indicates the use of a continuous-circuit transfer method; or if an interrupted-circuit transfer must be used, delay to the point where the bus residual voltage has decayed to a low enough value to prevent excessive inrush currents. In terms of bus transfer conditions, the routine cases should be done by the continuous-circuit method, the emergency case by the delayed interrupted-circuit transfer method.

Under the second criterion, the output or control of the generating unit is best assured by continuous-circuit transfer. This is feasible for the routine case in most station designs; but, where there can be a large phase difference between sources, it may not be possible to parallel them and an interrupted-circuit transfer is required. In any design, an interrupted-circuit transfer is necessary for the emergency case, and the second criterion suggests that the shorter the delay, or dead time, the better.

It is apparent that for the routine case a continuous-circuit transfer best satisfies both criteria; and unless, as previously mentioned, other factors prevent its application, it is the logical choice. But for the emergency case, the requirements of motor duty and boiler operation are in opposition, and the effect of the alternate transfer methods must be evaluated before a choice can be made.

Motor Duty

The effect of interrupted-circuit transfer on motor duty may be stated approximately in terms of the residual motor

Paper 55-96, recommended by the AIEE Power Generation Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 21, 1954; made available for printing November 18, 1954.

D. G. Lewis and W. D. Marsh are with the General Electric Company, Schenectady, N. Y.

Table I. Motor Constants for a 4,160-Volt Bus of a Typical Large, High-Pressure, High-Temperature Generating Unit

Motor	Type	No. of Motors	Horsepower	Kilovolt-Amperes	x	Open-Circuit Time Constant	Short-Circuit Time Constant	H
1	Boiler feed pump	2	2,500	2,160	0.16	3.6	0.12	2.5
2	Induced draft fan	2	1,250	1,140	0.16	1.0	0.058	10.0
3	Forced draft fan	2	600	530	0.16	1.25	0.048	4.5
4	Pulverizer and fan	5	300	280	0.16	0.5	0.037	7.5
5	Condensate pump	2	450	400	0.16	1.2	0.041	0.8
6	Service water pump	1	300	270	0.16	1.2	0.037	0.8
7	Circulating water pump	2	400	370	0.16	0.75	0.04	0.8
8	480-volt transformer	2		1,000	0.16*	0.5*	0.025*	1.0*
9	480-volt transformer	1		750	0.16*	0.5*	0.025*	1.0*

The values of x and H are in per unit on the individual motor kilovolt-ampere base; the time constants are in seconds. For the study of reacceleration, the secondary source is assumed to be a 12,500-kva transformer, with impedance on its own kilovolt-ampere base of 0.055 per unit.

* These values are assumed so that the transformers and their loads can be treated as equivalent motors in the calculation.

Table II. Motor Constants for Equivalent Motors Formed by Lumping Motors of Table I

Motor	Horsepower	Kilovolt-Amperes	x	Open-Circuit Time Constant	Short-Circuit Time Constant	H
1	5,000	4,320	0.505	3.6	0.12	0.685
2, 4	4,000	3,680	0.592	0.81	0.05	2.03
3	1,200	1,060	2.06	1.25	0.048	0.296
5–9	5,700	4,560	0.590	0.705	0.031	0.249

Values of x and H are in per unit on a base equal to the sum of the motor kilovolt-ampere ratings (13,620 kva).

voltage existing at the time the secondary source circuit breaker is closed. Experience has shown that if this voltage is 25 per cent of the rated voltage, or less, the inrush-current magnitude will be low enough to avoid excessive stresses on the windings. Motors of different voltage, speed, and horsepower rating vary in their ability to withstand winding stresses; but this rule is adequate to protect the most critical motors normally found on steam-station auxiliary busses.

BOILER OUTPUT AND CONTROL

The effect of interrupted-circuit transfer on boiler output and control is primarily a question of the speed-time relationships of the essential auxiliaries during the transfer. No attempt will be made to define limits of auxiliary speed and time for successful operation, because they vary widely with different boiler and boiler auxiliary designs, steam conditions, and types of fuel. But it should be possible to determine, for any particular station design, what auxiliary is limiting (pulverizer, draft fan, or boiler feed pump), at what minimum speed, and for what maximum time it may be allowed to operate without adversely affecting boiler operation. In many cases it will be possible by proper design and selection of auxiliaries to minimize the effect of reduced speed during transfer.

SELECTION OF BUS-TRANSFER METHODS

The most direct and practical way of protecting motors against excessive duty during interrupted-circuit transfer is to use an undervoltage relay on the motor bus to block closure of the secondary source circuit breaker until residual voltage has decayed to 25 per cent of normal. To predict the effect of this delay on boiler operation, however, it is necessary to know the time required for voltage decay, and the speeds of the auxiliaries during the dead time. It is also necessary to know the time required for reacceleration of the auxiliaries after the secondary source voltage has been applied. Approximate methods of determining these speeds and times as well as expressions for the transient torques and currents in the motors are presented later in the paper.

When, in the emergency case, it is determined that the speeds and times involved in a delayed interrupted-circuit transfer will not assure adequate boiler output or control, it may be necessary to resort to a nondelayed transfer. Where such transfers are truly emergency automatic operations occurring only rarely, experience indicates that motors can be expected to give reasonable service.

However, for the routine case, where it may not be possible to parallel sources, a nondelayed interrupted-circuit transfer should not be used. The frequency of transfer in the routine case would damage motor windings in a very short time. Since this transfer can be planned for times when loads are light, the use of delayed transfer will not ordinarily jeopardize boiler functions.

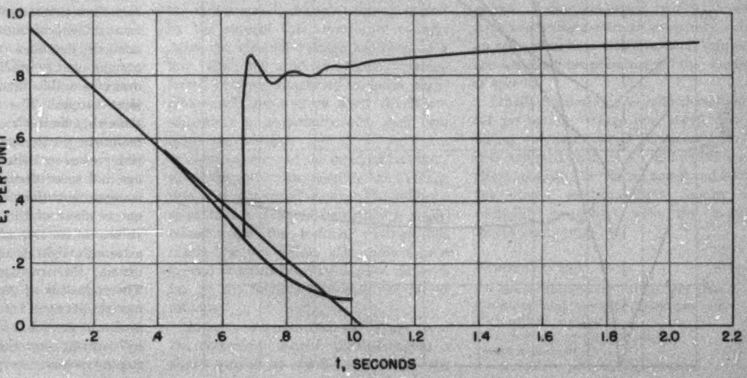

Fig. 1. Bus residual voltage decay and recovery. Motor constants given in Table II. Straight-line decay is calculated using curves of Fig. 4

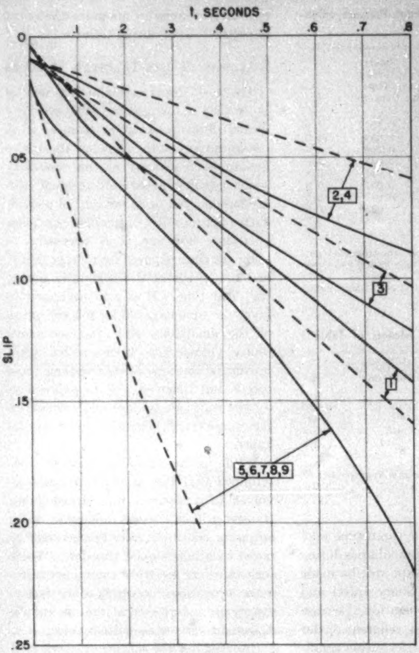

Fig. 2 (left). Motor speed decays. Primary source voltage removed at t=0. Motor constants given in Table II. Dotted curves show speed decays which would occur if motors were separately open-circuited

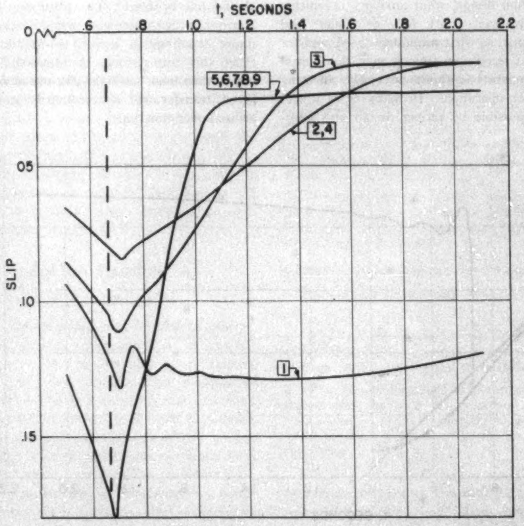
Fig. 3 (below). Motor speed recovery. Secondary source connected at t=0.667 second. Motor constants given in Table II



Discussion of Results

The basis for the results shown in the paper and the approximate methods which are suggested in the section entitled "Analysis" consist of a number of step-by-step calculations made using the equations of Appendix II. The calculations were made with an International Business Machines card programmed calculator, and they include a number of runs involving two, three, and four induction motors. As a starting point, typical machine constants for the auxiliaries associated with a large, high-temperature high-pressure unit were selected, as shown in Table I. The machines on this bus were then lumped into four equivalent machines, as shown in Table II.

Fig. 1 shows the decay of the magnitude of the bus residual voltage obtained from the step-by-step calculation for this case as well as a straight-line approximation obtained by using the curves of Fig. 4. Also shown in Fig. 1 is the magnitude of the bus voltage following reapplication of a secondary source at $t=0.667$ second.

Fig. 2 shows the decay in speed of the four lumped motors of Table II. Also shown are the speed decays which each of these motors would experience if they were open-circuited. This figure shows the tendency to synchronize which is maintained until the residual voltage has decayed to about 25 per cent of rated value. Fig. 3 shows the speeds of the four lumped motors following reapplication of secondary source voltage at $t=0.667$ second.

A large number of additional calculations have been made involving two and three machines. It seems reasonable that the quantities of interest, voltage, and speed decay should follow a pattern depending on certain fundamental parameters characteristic of a particular arrangement of motors. The following analysis describes the methods which may be used to predict voltage and speed decay as well as inrush current and transient torque. The analysis considers a somewhat limited range of parameters to make the predictions as accurate as possible; even so, estimates of rates of voltage and speed decay must be considered as approximations. In cases in which one or more of the motors has extreme values in its list of constants, such as extremely light load or unusually high inertia, the error may be appreciable. The equations of Appendix II give correct results even for extreme cases, so it is always possible to evaluate a situation by carrying out the complete step-by-step procedure.

Analysis

Physical Considerations

The study of bus transfer of a group of dissimilar auxiliary induction motors logically divides itself into the analysis of four periods of time:

1. The steady-state period preceding the removal of the primary source.

2. The first part of the dead time when the residual voltage is appreciable.

3. The secondary part of the dead time after the residual voltage has decayed to a negligible value.

4. The reacceleration period following the connection of the secondary source.

There is no sharp distinction between the first and second part of the dead time, since the decay of residual voltage is gradual. It is convenient, however, to analyze the two periods separately because, after the residual voltage has reached about 25 per cent of its rated value, further energy transfer between machines is negligible. In the second part of the dead time each motor can be treated separately, thus making the calculation of individual motor speeds much simpler than in the first part when the motors must be treated as a group.

The transformer feeding the auxiliary bus will normally be selected so that in the steady state prior to transfer the motor terminal voltage will have its rated value. Calculation of motor currents and slip in the steady state can be made using the familiar equivalent circuit; this calculation will not be discussed.

At the time of interruption each of the motors has a certain amount of stored energy: mechanical energy stored in the inertia of motor and load, and electromagnetic energy stored in the magnetic field. Quantitatively, the stored mechanical energy predominates; the electromagnetic energy in per unit is of the order of the current squared times the short-circuit reactance, while the mechanical energy is equal to the per-unit inertia constant of the machine. With no external source, the machines decelerate as their stored mechanical energy is used to supply the load. If all the motors and loads are identical, electrically and mechanically, they will decelerate at identical rates. No current will flow in the stator circuits, since each motor will see at its terminals a voltage equal to its own generated electromotive force (emf). This condition is just as if each motor were open-circuited. The speed decays at a rate determined solely by the load and the inertia of motor and load. The rotor flux decays exponentially according to the open-circuit time constant, and the residual voltage decays as the product of the rotor flux and the speed.

If the motors on the bus are not identical, the situation is altogether different. A motor with inertia greater than the average will decelerate more slowly and, as long as its rotor flux remains appreciable, it will act as an induction generator supplying energy to other motors having inertias smaller than the average. The effect of this energy transfer between machines is threefold:

1. The motors tend to synchronize; high-inertia motors are pulled down in speed as they supply energy to low-inertia machines.

2. The bus residual voltage decays at a rate faster than in the open-circuit case; the higher rotor currents caused by energy transfer between machines dissipate the magnetic energy in the rotors more rapidly.

3. The bus residual voltage and the individual motor fluxes all decay at very nearly the same rate. Any machine in which the flux tends to decay more rapidly than the average will receive excitation from the other machines.

There is a very short period of adjustment, about 3 cycles, immediately after the removal of the primary source. Initially, the bus frequency drops to a value corresponding to the average of the motor speeds, and then the angle of the bus voltage shifts behind the angle of the rotor flux in the high-inertia machines so that these machines supply electric torque to the low-inertia machines. This period of readjustment is included in the first part of the dead time.

After the short period of readjustment, the bus residual voltage and the motor fluxes decay at nearly equal rates. While the residual voltage is still appreciable, there is energy transfer from high-inertia machines to low-inertia machines, and the motor speeds decay at rates dictated by the rate of this transfer of energy. After the residual voltage has reached a low value, the amount of energy transferred between machines becomes negligible and the motors then decelerate separately in accordance with their own loads and inertias.

The frequency of the residual bus voltage decays at a rate equal to the average rate of motor speed decay. Calculations show that a common frequency is maintained until the residual voltage has reached a low value, after which time several frequencies may appear, depending on the relative speeds of the larger motors.

After the reapplication of voltage from the secondary source, there is again a short period of readjustment as the motor fluxes shift to positions behind the angle of the bus voltage. After this period, the motors will accelerate or continue to decelerate depending upon the bus voltage and the individual motor load characteristic. Since the motor terminal voltage will be appreciably less than its rated value because of the high motor currents, some of the motors may not develop sufficient electric torque to overcome load torque at their particular speeds. This condition may change as the less heavily loaded motors reach steady-state speed and their currents decrease to steady-state values. On the other hand, if the secondary source reactance is too high, large, low-resistance motors may not reaccelerate even after all other motors have reached steady-state speed.

Assumptions

The analysis from which the results presented in this paper are obtained is based on fundamental assumptions regarding the description of an induction machine. They are the same assumptions used by Stanley:[3]

1. Balanced rotor and stator windings are assumed.

2. It is assumed that the coefficient of mutual inductance between any stator winding and any rotor winding is a cosinusoidal function of the electrical angle between the axes of the two windings.

3. It is assumed that the rotor is smooth and that the self-inductances of all windings are independent of rotor position.

4. The effects of saturation, hysteresis, and eddy currents are neglected.

It is further assumed in the analysis that stator losses and d-c transients in the stators can be neglected, in so far as their effect on net electric torque is concerned. Appendix I contains a derivation of simplified motor equations which result from neglecting d-c stator transients. As an approximation, all motor load torques are assumed proportional to the square of speed.

Finally, in deriving simplified methods for predicting voltage and speed decay during the first part of the dead period, it is assumed that, in an induction machine operating near rated speed and load, the stored electromagnetic energy is negligible compared with the stored mechanical energy.

Nomenclature

a = motor horsepower rating, per unit
b = motor load, on motor base, per unit
e = terminal voltage
f = frequency, cycles per second
i = rotor current
p = derivative with respect to time

r = resistance of each equivalent rotor winding
s = slip
t = time, seconds
x = locked-rotor reactance
E = motor bus voltage
E' = voltage back of external reactance
H = inertia constant
I = stator current
I' = transient value of stator current
I_c = value read from the curve based on unit voltage
L = inductance
M = mutual inductance
R = resistance of each stator winding
T = time constant
T_{eff} = effective mechanical time constant
ΔT = measure of mechanical dissimilarity* between the motors
T_e = electric torque
T_m = load torque
θ = rotor position
Ψ = stator flux linkages
ψ = rotor flux linkages
Δ = difference

Subscripts

1, 2, 3 = phase arranged in order of rotor rotation
a, b, c = same as 1, 2, 3
$\alpha, \beta, 0$ = transformed components
r = rotor
s = stator
0 = at time zero
T = total
A = average
C = read from curve
e = external

All quantities, unless otherwise specified, are expressed in per unit on a base common to all machines. A convenient base is the total rated kilovolt-amperes of the motors on the bus. Weighted averages are used at several points in the analysis. It is necessary to give some consideration to the method of weighting to obtain the best estimate of the physical situation. In calculating the quantity ΔT, the per-unit motor load ab is used as a weighting factor. On the other hand, in calculating the bus average x/r ratio, it is felt that the best estimate will be obtained by using the per-unit motor rating a as a weighting factor.

BUS RESIDUAL VOLTAGE

It was pointed out earlier that if all the motors and loads on the bus are identical, each will act as if it were open-circuited, and the bus voltage will decay in accordance with the machines' open-circuit time constant. Complete step-by-step calculations of motor behavior during the dead period show that with dissimilar machines on the bus:

1. The rate of voltage decay is more rapid than the product of motor speed and an exponential decay based on the open-circuit time constant.
2. The bus residual voltage and the motor fluxes all decay at nearly the same rate.
3. The rate of voltage decay is greatest for motor combinations with the most pronounced mechanical dissimilarities.
4. If the postswitching value of residual voltage is taken as a starting point, the decay can be fairly well approximated by a straight line down to about 25 per cent of the rated voltage.
5. For combinations having the same degree of mechanical dissimilarity, the decay is roughly proportional to the average x/r ratio of the motors.

These observations lead to the conclusion that the voltage decay during the first part of the dead period can be calculated by assuming a straight line starting at the postswitching value of voltage. This postswitching value of voltage can be found with satisfactory accuracy by assuming all the motors to be lumped as one equivalent motor having average electrical characteristics, and calculating the back emf of this equivalent motor from the simple steady-state equivalent circuit. The slope of the straight line is related to the average x/r of the motors and to the degree of mechanical dissimilarity. To evaluate the relationship which exists, it is necessary to establish a measure of the mechanical dissimilarity.

If a motor decelerates with no electric torque present, its slip at any time is given by

$$s = s_0 + \frac{1}{4\pi f H}\int T_m dt \tag{1}$$

It is assumed that

$$T_m = ab(1-s)^2 \tag{2}$$

therefore

$$s = s_0 + \frac{ab}{4\pi f H}\int (1-s)^2 dt \tag{3}$$

Differentiating and separating the variables

$$t = \frac{4\pi f H}{ab}\left(\frac{1}{1-s} - \frac{1}{1-s_0}\right)$$
$$= 4\pi f T\left(\frac{1}{1-s} - \frac{1}{1-s_0}\right) \tag{4}$$

With this equation the speed decay for a single motor acting alone can be calculated. It can be seen that the significant mechanical parameter is the ratio $H/ab = T$, having the dimensions of seconds. If the load torque were directly proportional to speed, this ratio would appear in the speed equation as a time constant in the familiar sense.

In general, all of the motors on the bus will have different T ratios. Since all the H's and all the a's are expressed in per unit on a common base, it is correct to say that the ratio $[H_T/(ab)_T] = T_A$ is the mechanical parameter which expresses the central tendency or average of the bus.

Now suppose that all the motors on the bus are assigned new electrical parameters such that all motors are electrically identical with the bus average. Since all the motor fluxes decay at nearly the same rate, this step is justified. Suppose further that all the motors with T greater than T_A are lumped into one equivalent motor having $(T-T_A)$ equal to the mean $(T-T_A)$ of the individual motors; a second equivalent motor is assigned (T_A-T) equal to the mean (T_A-T) of the motors with T less than T_A. Step-by-step calculations show that this hypothetical combination of equivalent motors gives approximately the same rate of voltage decay as the combination from which the equivalents are derived. This fact provides a measure of the mechanical dissimilarity or dispersion of mechanical parameter about the average. Define the quantity ΔT

$$\Delta T = \frac{\Sigma(T_i - T_A)(a_i b_i)}{(ab)_T} \tag{5}$$

In other words, ΔT is the weighted average of the absolute magnitudes of the $(T-T_A)$ values for all the motors.

Fig. 4 shows the relationship between the bus average x/r ratio, the ratio $\Delta T/T_A$, the ratio of total load $(ab)_T$ to total rating a_T, and the slope of the straight-line approximation to the emf decay. These curves were plotted using data obtained in a step-by-step calculation as described in Appendix II.

SPEED DECAY

It is pointed out earlier that there is a very short period of readjustment following the removal of primary source voltage, followed by a period during which the individual motors tend to synchronize because of the energy transfer between high- and low-inertia machines. During both these periods, which together constitute the first part of the dead period, the individual motor speeds can be fairly well approximated by curves of the form given by equation 4, with T replaced by T_{eff} For any motor, T_{eff} will depend on the motor T, the bus average, T_A, and the bus average x/r ratio. Values of T_{eff} can be found from Fig. 5, which relates the rato T/T_{eff} to the quantities T/T_A and bus average x/r. The speed decay based on T_{eff} holds until the bus residual voltage has reached about 25 per cent of rated value. After this time, the motors act independently, and the actual motor T must be used in equation 4.

TIME FOR MOTOR REACCELERATION

Since the rates of acceleration after the reapplication of voltage are relatively

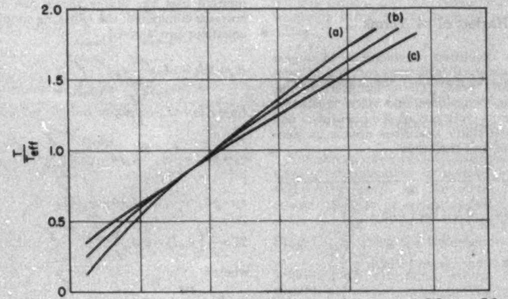
Fig. 6 (above). Co-ordinate axes used to derive motor equations. The α and β axes are rotating at synchronous speed in the direction of rotor rotation



slow and since there is little exchange of energy between motors during this period, it is sufficient to analyze the speed recovery with a step-by-step calculation based on the individual motors' speed-torque and speed-current curves. In fact, such a calculation should be better than one based on the equations of Appendix II, because motor reacceleration at low terminal voltages is sensitive to differences between the idealized speed-torque curve and the actual speed-torque curve which accounts for the effects of variation of rotor resistance with frequency.

All the motors must be considered at once for the reduced bus voltage to be calculated correctly; however, similar motors may be lumped together using the method of Appendix III, so that the final number of motors to be considered may be as small as three or four. Also, as an approximation, phase differences between the various motor currents can be disregarded. The time interval associated with this step-by-step calculation can be fairly long, say 0.25 second, provided a sufficient accurate method of numerical integration is used. A suggested procedure is given in Appendix IV.

INRUSH CURRENTS AND TRANSIENT TORQUES

Appendix V gives as the expected magnitude of the inrush current (fully offset)

$$I'=\frac{\Delta E}{x} \tag{6}$$

In the worst case, ΔE is equal to the sum of the magnitudes of the preswitching bus residual voltage and the postswitching bus voltage. Then

$$I'=\frac{E_0+E'}{x\left(1+x_e\sum\frac{1}{x}\right)} \tag{7}$$

Equation 7 gives the transient value of

current. After a period of time determined by the bus average x/r ratio, or short-circuit time constant, the current to any motor reaches the value given by the steady-state characteristics for the particular speed and bus voltage.

The postswitching value of electric torque for any motor consists of a steady component plus a unit-frequency pulsating component. Appendix V gives as the approximate value of the maximum total torque

$$T_e'=\frac{E_0}{x}\left(E+\sqrt{E^2+E_0^2}\right) \tag{8}$$

where

$$E=\frac{E'}{1+x_e\sum\frac{1}{x}} \tag{9}$$

Appendix I. The Equations of the Induction Motor Referred to Synchronously Rotating Axes

Under the first four assumptions of the analysis and with reference to Fig. 6, the fundamental stator and rotor emf equations are written as follows

Stator

$$e_a=p\psi_a+Ri_a$$
$$e_b=p\psi_b+Ri_b$$
$$e_c=p\psi_c+Ri_c$$

Rotor

$$e_1=p\psi_1+ri_1=0$$
$$e_2=p\psi_2+ri_2=0$$
$$e_3=p\psi_3+ri_3=0 \tag{10}$$

In Fig. 6, the α and β axes are rotating in the direction of rotor rotation at unit or synchronous speed such that the positive α axis coincides with the center of the positive a-phase winding at time zero.

The winding self- and mutual per-unit inductances are defined by the following flux-linkage equations

$$\psi_a=L_s'i_a+M_s'(i_b+i_c)+M'\left[i_1\cos(t+\theta)+i_2\cos\left(t+\theta+\frac{2\pi}{3}\right)+i_3\cos\left(t+\theta-\frac{2\pi}{3}\right)\right]$$
$$\psi_b=L_s'i_b+M_s'(i_c+i_a)+M'\left[i_1\cos\left(t+\theta-\frac{2\pi}{3}\right)+i_2\cos(t+\theta)+i_3\cos\left(t+\theta+\frac{2\pi}{3}\right)\right]$$
$$\psi_c=L_s'i_c+M_s'(i_a+i_b)+M'\left[i_1\cos\left(t+\theta+\frac{2\pi}{3}\right)+i_2\cos\left(t+\theta-\frac{2\pi}{3}\right)+i_3\cos(t+\theta)\right] \tag{11}$$
$$\psi_1=L_r'i_1+M_r'(i_2+i_3)+M'\left[i_a\cos(t+\theta)+i_b\cos\left(t+\theta-\frac{2\pi}{3}\right)+i_c\cos\left(t+\theta+\frac{2\pi}{3}\right)\right]$$
$$\psi_2=L_r'i_2+M_r'(i_3+i_1)+M'\left[i_a\cos\left(t+\theta+\frac{2\pi}{3}\right)+i_b\cos(t+\theta)+i_c\cos\left(t+\theta-\frac{2\pi}{3}\right)\right]$$
$$\psi_3=L_r'i_3+M_r'(i_1+i_2)+M'\left[i_a\cos\left(t+\theta-\frac{2\pi}{3}\right)+i_b\cos\left(t+\theta+\frac{2\pi}{3}\right)+i_c\cos(t+\theta)\right]$$

The quantities in equations 10 and 11 can be referred to the α and β axes by means of the following transformation[4]

$$i_a=I_\alpha\cos t-I_\beta\sin t+I_0$$
$$i_b=I_\alpha\cos(t-2\pi/3)-I_\beta\sin(t-2\pi/3)+I_0$$
$$i_c=I_\alpha\cos(t+2\pi/3)-I_\beta\sin(t+2\pi/3)+I_0$$
$$i_1=i_\alpha\cos\theta+i_\beta\sin\theta+i_0 \tag{12}$$
$$i_2=i_\alpha\cos(\theta+2\pi/3)+i_\beta\sin(\theta+2\pi/3)+i_0$$
$$i_3=i_\alpha\cos(\theta+2\pi/3)+i_\beta\sin(\theta+2\pi/3)+i_0$$

Equations of the same form are applied to the stator and rotor emf's and flux linkages. In addition, the following definitions are made

$$L_s=L_s'-M_s'=\text{apparent stator self-inductance}$$
$$L_r=L_r'-M_r'=\text{apparent rotor self-inductance} \tag{13}$$
$$M=3/2M'=\text{apparent mutual inductance}$$

In the transformations 12 it is necessary to define six new variables to replace each six original variables; however, it is evident that I_0 and i_0 (and similarly Ψ_0 and ψ_0, E_0 and e_0) vanish if the restriction of balanced operation is applied.

Substituting the currents, flux linkages, and voltages from transformations 12 and the inductances from equations 13 into equations 10 and 11

$$E_\alpha=p\Psi_\alpha+RI_\alpha-\Psi_\beta \qquad \Psi_\alpha=L_sI_\alpha+Mi_\alpha$$
$$E_\beta=p\Psi_\beta+RI_\beta+\Psi_\alpha \qquad \Psi_\beta=L_sI_\beta+Mi_\beta$$
$$E_0=p\Psi_0+RI_0 \qquad \Psi_0=(L_s'+2M_s')I_0$$
$$\tag{14}$$
$$e_\alpha=p\psi_\alpha+ri_\alpha+\psi_\beta p\theta=0 \qquad \psi_\alpha=L_ri_\alpha+MI_\alpha$$
$$e_\beta=p\psi_\beta+ri_\beta-\psi_\alpha p\theta=0 \qquad \psi_\beta=L_ri_\beta+MI_\alpha$$
$$e_0=p\psi_0+ri_0=0 \qquad \psi_0=(L_r'-2M_r')i_0$$

The electric torque is given by the following[5]

$$T_e=\psi_\beta i_\alpha-\psi_\alpha i_\beta$$

The Neglect of pΨ Terms

The quantities in equations 14 appear as if observed from axes rotating at synchronous speed. The consequence of this is that symmetrical a-c stator quantities appear as constants or d-c quantities, and that d-c stator quantities appear as sinusoids at unit frequency.

When a short-circuit or other switching transient occurs in an induction motor circuit, there appears a transient offset in the stator currents and flux linkages. This offset arises from the fact that stator flux linkages cannot jump to a new value in zero time when a switching operation occurs. The d-c stator current which results causes an oscillatory torque. Because of the relatively high inertia of the motor, this torque will have no appreciable effect on rotor speed. In studying motor transients involving relatively slow speed changes, it is desirable to neglect the d-c offset and the oscillatory torque produced by it.

To neglect the transient d-c offset, stator flux linkages cannot be continuous, but stator quantities must be related to each other on a symmetrical basis at all times. In equations 14, the terms preventing jumps in stator linkages are the $p\Psi$ terms in the first two equations; a jump presents an undefined derivative. Also, if stator currents, voltages, and linkages are symmetrical and in the steady state, $p\Psi_\alpha=p\Psi_\beta=0$; relatively slow changes in voltage, current, and linkage amplitudes admit $p\Psi_\alpha=p\Psi_\beta=0$ as an approximation. Omitting the $p\Psi$ terms in the first two equations of equations 14 is a simple way to eliminate the transient offset.

Differential analyzer studies made by the authors indicate that in investigations of motor transients involving appreciable speed changes the results are not significantly affected by the omission of the $p\Psi$ terms. In the stator currents, the offsets simply do not appear. Neither the rotor fluxes nor the net electric torque are appreciably changed.

The omission of the $p\Psi$ terms greatly simplifies the solution of the motor equations. From equations 14, with the $p\Psi$'s omitted and the stator fluxes and rotor currents eliminated, the following simplified equations are derived

$$E_\alpha=RI_\alpha-xI_\beta-\frac{M}{L_r}\psi_\beta$$
$$E_\beta=RI_\beta+xI_\alpha+\frac{M}{L_r}\psi_\alpha$$
$$e_\alpha=p\psi_\alpha+\frac{r}{L_r}\psi_\alpha+\psi_\beta p\theta-\frac{r}{L_r}MI_\alpha=0 \tag{15}$$
$$e_\beta=p\psi_\beta+\frac{r}{L_r}\psi_\beta-\psi_\alpha p\theta-\frac{r}{L_r}MI_\beta=0$$
$$T_e=\frac{M}{L_r}\left(\psi_\alpha I_\beta-\psi_\beta I_\alpha\right)$$

where

$$x=L_s-\frac{M^2}{L_r}$$

Appendix II. The Equations for Several Induction Machines Fed Through a Common Reactance

Equations 15 may be modified for use in the study of several induction machines connected together and fed through a common reactance. In this case, E_α and E_β will be the motor bus emf common to all machines. They will no longer be constants, but will be functions of the total bus current, i.e., if E_α' is a constant emf back of the common reactance x_e, then

$$E_\alpha=E_\alpha'+x_e\sum I_\beta \tag{16}$$

and similarly

$$E_\beta=E_\beta'-x_e\sum I_\alpha$$

For any one motor, equations 15 give

$$I_\alpha=\frac{E_\beta}{x}-\frac{M}{L_r}\frac{\psi_\alpha}{x}-\frac{R}{x}I_\beta$$

$$I_\beta=-\frac{E_\alpha}{x}-\frac{M}{L_r}\frac{\psi_\beta}{x}+\frac{R}{x}I_\alpha \tag{17}$$

so that

$$\begin{aligned}\sum I_\alpha&=E_\beta\sum\frac{1}{x}-\sum\frac{M}{L_r}\frac{\psi_\alpha}{x}-\sum\frac{R}{x}I_\beta\\ \sum I_\beta&=-E_\alpha\sum\frac{1}{x}-\sum\frac{M}{L_r}\frac{\psi_\beta}{x}+\sum\frac{R}{x}I_\alpha\end{aligned} \tag{18}$$

A further simplification in the motor equations can be affected by omitting the stator loss terms in equation 18. Since R/x is 0.1 or smaller, the error in the currents introduced by this simplification should be 1 per cent or less. The usefulness of this approximation has been checked in differential analyzer studies with good results.

Omitting the R/x terms, and substituting the currents from equation 18 into equation 16 results in

$$E_\alpha=E_\alpha'-x_eE_\alpha\sum\frac{1}{x}-x_e\sum\frac{M}{L_r}\frac{\psi_\beta}{x}$$

$$E_\beta=E_\beta'-x_eE_\beta\sum\frac{1}{x}+x_e\sum\frac{M}{L_r}\frac{\psi_\alpha}{x}$$

Solving for the bus voltages

$$\begin{aligned}E_\alpha&=\frac{\dfrac{E_\alpha'}{x_e}-\sum\dfrac{M}{L_r}\dfrac{\psi_\beta}{x}}{\dfrac{1}{x_e}+\sum\dfrac{1}{x}}\\ E_\beta&=\frac{\dfrac{E_\beta'}{x_e}+\sum\dfrac{M}{L_r}\dfrac{\psi_\alpha}{x}}{\dfrac{1}{x_e}+\sum\dfrac{1}{x}}\end{aligned} \tag{19}$$

Equations 19 make the step-by-step solution of the multimachine problem quite simple. The third and fourth equations of the equation 15 can be solved for the rotor flux-linkage time derivatives to form a basis for whatever type of prediction equation is to be used. The flux prediction must be made for each motor. Equations 19 then give the motor bus voltages in terms of the source voltage and the predicted motor fluxes. The individual motor currents can then be found from equations 17 and the torque can be calculated. The speed is found from the acceleration equation

$$p\theta=\frac{1}{4\pi fH}\int(T_e-T_m)dt \tag{20}$$

where the mechanical torque T_m is a given function of speed. The advantage of solving for the bus voltage separately as in equations 19 is that with this arrangement the numerical difficulty of the solution increases somewhat less than linearly with the number of motors involved.

Appendix III. Lumping of Motors With Similar Characteristics

To reduce the number of machines which must be considered in studying a particular case, it is usually necessary to lump together machines with similar characteristics so that the resulting equivalent machine will have the same effect on the remainder of the system as the original machines acting individually. In this study of bus transfer, the following procedure is used:

1. All motor constants including inertia constants and loads are expressed in per unit on a common base.
2. The individual load torques and inertia factors are added together to form an equivalent load torque and inertia factor.
3. The locked-rotor or short-circuit reactances are combined as if connected in parallel.
4. The rotor resistance and the stator and rotor self- and mutual inductances are calculated using the criteria that the stator and rotor self-inductances are equal and that the equivalent machine must have short-circuit and open-circuit time constants equal to the weighted averages of the time constants of the original machines, weighting being on the basis of machine rating.

Appendix IV. Step-by-Step Method for the Calculation of Motor Reacceleration

For the purpose of this discussion, the time of reapplication of voltage will be called time zero. All the motor speeds are presumed to be known at this time.

Step 1. Starting the Calculation

Using the individual motor speed-current curves, the motor currents can be found in the form

$$I=\frac{E}{1}I_e \tag{21}$$

The voltage at the bus can be found from

$$E=\frac{E'}{1+x_e\sum I_e} \tag{22}$$

The electric torque can now be found from the individual speed-torque curves, the actual value being given by

$$T_e=\frac{E^2}{1}T_e \tag{23}$$

where T_e is the value from the curve. The first approximation to the increase in speed during the first time interval is

$$\Delta(p\theta)=\frac{\Delta t}{2H}\left(T_e-T_m\right) \tag{24}$$

This value of $\Delta(p\theta)$ is next improved by calculating the currents and torques for $p\theta=(p\theta)_0+\Delta(p\theta)$ and averaging the accelerating torque with the original value. This manner of improvement can be repeated if it appears necessary.

Step 2. Continuing the Calculation

Once the values of $p\theta$'s at $t=\Delta t$ have been found, the calculation of successive points is simpler. The value of $\Delta(p\theta)$ between $t=0$ and $t=\Delta t$ is assumed to apply also between $t=\Delta t$ and $t=2\Delta t$ and the average accelerating torque in the second interval is calculated on this basis. This torque is then used to calculate an improved $\Delta(p\theta)$ and the calculation proceeds to the next point.

Appendix V. Modified Equations for the Calculation of Inrush Currents and Transient Torques

When voltage from the secondary source is reapplied to the motor bus, each motor will experience high inrush currents and transient unit-frequency torques. To calculate the initial magnitudes of these currents and torques, equations 14 may be modified by assuming motor speeds constant and neglecting all resistances.

With these simplifications, and with stator flux linkages and rotor currents eliminated

$$\begin{aligned}&xpI_\alpha+\frac{M}{L_r}p\psi_\alpha-xI_\beta-\frac{M}{L_r}\psi_\beta=E_\alpha\\ &xI_\alpha+\frac{M}{L_r}\psi_\alpha+xpI_\beta+\frac{M}{L_r}p\psi_\beta=E_\beta\\ &p\psi_\alpha+(p\theta)\psi_\beta=0\\ &-(p\theta)\psi_\alpha+p\psi_\beta=0\end{aligned} \tag{25}$$

These equations may be solved operationally, giving for the currents and flux linkages

$$\begin{aligned}I_\alpha&=\frac{1}{x}\Bigg[E_\beta(1-\cos t)+\left(E_\alpha+xI_{\beta0}+\frac{M}{L_r}\psi_{\beta0}\right)\sin t+\left(xI_{\alpha0}+\frac{M}{L_r}\psi_{\alpha0}\right)\cos t+\frac{M}{L_r}\psi_{\beta0}\sin(p\theta)t-\frac{M}{L_r}\psi_{\alpha0}\cos(p\theta)t\Bigg]\\ I_\beta&=\frac{1}{x}\Bigg[-E_\alpha(1-\cos t)+\left(E_\beta-xI_{\alpha0}-\frac{M}{L_r}\psi_{\alpha0}\right)\sin t+\left(xI_{\beta0}+\frac{M}{L_r}\psi_{\beta0}\right)\cos t-\frac{M}{L_r}\psi_{\beta0}\cos(p\theta)t-\frac{M}{L_r}\psi_{\alpha0}\sin(p\theta)t\Bigg]\end{aligned} \tag{26}$$

$$\psi_\alpha=\psi_{\alpha0}\cos(p\theta)t-\psi_{\beta0}\sin(p\theta)t$$

$$\psi_\beta=\psi_{\alpha0}\sin(p\theta)t+\psi_{\beta0}\cos(p\theta)t$$

If it is assumed that the dead time is long compared to the machines' short-circuit time constants so that the motors may be considered as following steady-state characteristics (with slow deceleration) just prior to the reapplication of voltage, then equations 26 can be simplified to give for the currents

$$I_\alpha=\frac{1}{x}\left(\Delta E_\beta(1-\cos t)+\Delta E_\alpha \sin t\right)+I_{\alpha 0}$$

$$I_\beta=\frac{1}{x}\left(-\Delta E_\alpha(1-\cos t)+\Delta E_\beta \sin t\right)+I_{\beta 0} \tag{27}$$

in which ΔE_α and ΔE_β are the changes in motor terminal voltage through the switching operation. $I_{\alpha 0}$ and $I_{\beta 0}$ are the preswitching values of stator current.

By manipulating the terms in equations 27 it can be shown that the maximum inrush current will occur when the preswitching bus residual voltage and the newly applied voltage are 180 degrees out of phase. The magnitude of the symmetrical component of current in this case will be

$$I=\frac{\Delta E}{x}+I_0 \tag{28}$$

where ΔE equals the sum of the magnitudes of the newly applied terminal voltage and the preswitching value of bus residual voltage. To calculate the actual peak current it must be noted that the current given by the first term of equation 28 will be fully offset. For practical purposes, the I_0 term in equation 28 can be neglected.

Since slip at the end of the dead period is still relatively small, the flux linkages given by procedure 1 in Appendix III can be approximated by their preswitching values

$$\begin{aligned}\psi_\alpha&=\psi_{\alpha 0}\\ \psi_\beta&=\psi_{\beta 0}\end{aligned} \tag{29}$$

In terms of these variables, the electric torque is

$$T_e=\frac{M}{L_r}\left(\psi_\alpha I_\beta-\psi_\beta I_\alpha\right)$$

Substituting the currents and flux linkages from procedures 2 and 4 of Appendix III

$$T_e=\frac{1}{x}\left[\left(\frac{M}{L_r}\psi_{\beta 0}\Delta E_\beta+\frac{M}{L_r}\psi_{\alpha 0}\Delta E_\alpha\right)(1-\cos t)+\left(\frac{M}{L_r}\psi_{\beta 0}\Delta E_\alpha-\frac{M}{L_r}\psi_{\alpha 0}\Delta E_\beta\right)\sin t\right]+T_{e0} \tag{30}$$

T_{e0}, the electric torque prior to switching, will be small and can be disregarded. At the end of the dead time the stator currents will be small; therefore

$$\begin{aligned}\frac{M}{L_r}\psi_{\alpha 0}&=E_{\beta 0}\\ \frac{M}{L_r}\psi_{\beta 0}&=-E_{\alpha 0}\end{aligned} \tag{31}$$

Thus the initial torque can be written

$$T_e=\frac{1}{x}\left[(-E_{\alpha 0}\Delta E_\beta+E_{\beta 0}\Delta E_\alpha)(1-\cos t)+(-E_{\alpha 0}\Delta E_\alpha-E_{\beta 0}\Delta E_\beta)\sin t\right] \tag{32}$$

The torque given by equation 32 can be separated into a unidirectional torque and a unit-frequency oscillatory torque.[6] The maximum value of the unidirectional torque occurs when the preswitching bus residual voltage and the newly applied voltage are 90 degrees out of phase. This value is given by

$$T_1=\frac{EE_0}{x} \tag{33}$$

where E_0 is the magnitude of the preswitching residual voltage and E is the magnitude of the newly applied terminal voltage.

The maximum value of the oscillatory torque occurs when E and E_0 are 180 degrees out of phase at the time of switching. This value is given by

$$T_2=\frac{(\Delta E)(E_0)}{x} \tag{34}$$

For values of E_0 below 30 per cent of the value of the newly applied terminal voltage, the maximum total torque occurs when E and E_0 are approximately 90 degrees out of phase. Its value is approximately

$$T=\frac{E_0}{x}\left(E+\sqrt{E^2+E_0^2}\right) \tag{35}$$

◆

Discussion

W. F. Mackenzie (Pennsylvania Power & Light Company, Hazelton, Pa.): The authors are to be congratulated for having presented an excellent method for calculating conditions occurring under an interrupted bus transfer. The paper provides an excellent qualitative discussion of the electrical and mechanical behavior of the equipment during the transfer. It also provides the means to obtain quantitative results for any given system. The calculations involved may be rather laborious for the engineer confronted with the design of a power plant auxiliary transfer scheme. It may be more practical to make oscillograph tests on the auxiliary system after it is assembled and design the transfer scheme from these results.

Since our company has been using the nondelayed interrupted transfer for all emergency transfers on its larger units for several years, we would be vitally interested to know the details on any motor failures that have occurred from this type of transfer.

L. R. Sellers (Tennessee Valley Authority, Knoxville, Tenn.): Mr. Lewis and Mr. Marsh have made a valuable contribution to this complex subject by their thorough analytical approach. With reference to the continuous-circuit transfer method recommended, the 0.055 per-unit transformer impedance used in Table I utilizes about 0.88 of a 250-megavolt-ampere circuit-breaker interrupting rating and all of this breaker's momentary 60,000-ampere rating. Paralleling two sources of this magnitude even for a short interval appears to be a questionable practice, particularly when the start and emergency transformer which should be connected electrically remote from the generator may be out of phase during unusual system conditions. The open-circuit method with a fixed time delay for routine transfers appears to be a better arrangement in most cases. This type of transfer can be made at full load when required.

The requirement that the residual bus voltage be limited to 25 per cent of rated voltage should be subject to a critical review since it will become unduly restrictive as the size of generating units and auxiliary motors increases. Steps leading to the establishment of this factor may have been brought about by deficiencies in motor design. Some of the motors installed recently were found to be insufficiently braced for full-voltage starting on a low-impedance supply system. Extensive transfer tests of all the auxiliaries for a 125-megawatt unit at the Tennessee Valley Authority Johnsonville plant did not indicate any apparent relation between asymmetric motor inrush and bus residual in the range of 4- to 36-per-cent residual. The higher motor impedance at 85 per cent speed as compared to the locked-rotor impedance actually tends to reduce the inrush value.

With reference to Fig. 1, the residual decay to 25 per cent in about 0.7 second is rather short for the size of motors as tabulated in Table I. Could this be attributed to an assumption that the motors were operating near name-plate rating before transfer instead of 80 to 85 per cent as in the usual case? During the transfer tests referred to in the foregoing, about 1.2 seconds were required to reach 25-per-cent residual with a total connected-motor load of 7,900 kva, including two 1,750-horsepower boiler feed motors.

Referring to Fig. 3, the poor recovery speed characteristics of a standard boiler feed motor led to the development with several manufacturers of 3,600-rpm motors with torque characteristics better matched to the pump requirements. Motors rated 2,000, 3,000, and 4,000 horsepower for use with 150-, 200-, and 250-megawatt units have been shop-tested to show accelerating torque characteristics at 75-per-cent rated volts such that they will have a definite accelerating torque above the pump requirements from zero to rated speed.

H. C. Barnes and **S. H. Horowitz** (American Gas and Electric Service Corporation, New York, N. Y.): The authors have presented an excellent theoretical examination of an interesting phase of motor protection. That operating practices which involve this problem are in use is well established.

There is no question that it is desirable to establish quickly auxiliary power from a reserve source in event of loss of the normal source from the generator. To do this quickly enough to assure safe shutdown requires automatic transfer. Any automatic scheme requires periodic testing to assure proper operation when needed. The best time to make this test is when the unit is being removed from service for maintenance or inspection. To make such a test with loadings of upwards of 200 megawatts would involve too great a service risk. To do so when removing a unit not only eliminates this risk but also saves numerous operations on the part of the operator. Also, the time of the test man is saved since the tripping is usually initiated from an emergency push button or from a protective relay contact which trips the differential, thereby testing not only the reserve transfer components but also the differential, main breaker, field breaker, and other devices. Therefore, it appears that this type of transfer will be encountered even though a transfer under actual fault conditions never occurs.

There has been some past discussion that the chance of motor damage from transfer is increasing because of the increased use of the automatic transfer as a "lazy" means of shutdown. Actually, modern generating-unit service continuity is so high that the desired test period is usually exceeded before a shutdown occurs. Therefore, there is actually little increase in the number of automatic transfers because this means is used for a routine shutdown.

After the initial shakedown period, the number of transfers because of fault conditions is very small. Also, in event of a fault, it is generally believed that the fault will act to diminish the residual voltage. Therefore, the risk of damage by reason of transfer from fault is slight.

While the paper is conclusive that theoretically there is danger of damage, practically this is questionable. Like all studies of this type, there are so many assumptions and so many variables that it always seems doubtful that the results are truly representative. For example, if it is assumed that the worst condition of full residual voltage continues, then, to cause damage, it is necessary to hit at some point considerably out of phase. If it is necessary for the angle to be greater than 90 degrees, which does not seem unresonable, then this factor alone reduces the probability 50 per cent.

Fig. 1 indicates that the inherent 20- to 25-cycle closing time of the large circuit breakers used on the incoming feeds is enough to permit voltage decay in the order of 60 to 50 per cent. This reduction means a larger angle necessary for danger and, therefore, reduces the angular area in which damage can occur. Reference 1 indicates that, at 20 cycles, the voltages are practically in phase.

Table I is fairly representative of the auxiliaries associated with a unit. However, this number of motors is in service only during full load. At the time of a normal shutdown only a few of these are in service, since the load would have been decreased to near zero and coal firing would have been discontinued. Those in service may well be practically unloaded, thereby reducing the decelerating torque and, therefore, the slip. An indication of the conditions is a typical reduction of auxiliary demand from 11,000 kw at full load to 3,000 kw at near no load. A check of planned outages of two 200-megawatt units revealed that only one forced draft fan, one boiler pump, and one circulating water pump were running. All pulverizers were down. It is, therefore, doubtful that the same motors will be stressed each shutdown. Further, pressure operation is proving so much better than suction that induced draft fans will seldom be used. This does however tend to increase the size of the forced draft fan. If larger drives are required, it is quite possible that they will be steam because of the increased over-all heat efficiency.

Even if it is assumed that the worst condition of full residual voltage at a 180-degree angle is encountered, this would appear negligible if the impedance of the source were equal to that of the load since only per-unit voltage would appear across each impedance. While this is rather impractical, there is some source impedance and the larger motor at least is nearer to this source impedance than the smaller motor. This may be insignificant but it is another factor which tends to limit the stress.

The paper states that experience has shown that residual voltage greater than 25 per cent of rated will cause excessive winding stress. Some detail of this experience would be appreciated.

Automatic transfer without intentional time delay has been in use by the American Gas and Electric Company system for over 15 years. Motor failure from mechanical winding stress has been very small. None are known to have been caused by automatic transfer. Motors of 2,500 horsepower have been in use for at least half of this period. A large number of 18,750-kva synchronous condensers have been transferred from starting to running without benefit of synchronizing or time delay and no damage has resulted. The latter may not be a fair example since it is effectively an unloaded motor, usually in hydrogen, and slip during transfer could be small. This experience does not indicate that the interrupted transfer is damaging enough to warrant much consideration.

Large motors are protected by plunger-type instantaneous relays. Seldom have these caused tripping during transfer. On a few test transfers, about 1950 it was found that a setting of 10 per cent greater than normally required for starting was needed for the 2,500-horsepower boiler feed pumps to assure 100-per-cent continuity on transfer. Even the need for this increase is questionable since it is not of too great consequence if one relay should trip as it can be readily restarted in time. The increase has not been used on the last five units and no tripping on transfer has resulted.

In speaking of winding stress, an explanation of the nature and degree of stress would be helpful. Presumably, the conductor tends to be driven through the insulation or forces out the retaining material. Is this force not distributed over the conductor area? What is the resultant pressure per square inch and how does this compare to the insulation strength in compression? Is it not reasonable that failure probably will not occur at the first stressing and that it may take several before actual insulation rupture occurs? If so, is it not possible that the required number of stresses may never be encountered in the life of the motor? If excessive inrush is encountered, the instantaneous relays would initiate tripping in about 1 cycle and clearing in another 4 or 5. Would not this tend to reduce the damage?

There has been some talk of possible shaft failure. This is not mentioned in the paper. Is this a real problem?

One of the principals of mechanical design used to be to calculate carefully the stresses and then multiply by a safety factor of roughly from 3 to 30, depending upon the damage possible. Is not some such safety factor still used, and if so, is it not sufficient to take care of these occasional stresses?

While the cost of adding time delay is insignificant, our experience has not been such to justify the nuisance value of test, maintenance burden increase, and added chance of transfer failure when needed. It may seem that these are so small as to be meaningless. It should be remembered that the ratio of really necessary gadgets per kilowatt to manpower per kilowatt is ever increasing. Therefore, any unnecessary ones should be avoided.

While we have not found it necessary, we are quite willing to change if it can be proved that our experience is unique. We would be quite interested in hearing the motor manufacturers statements as to their experience, design factors, and recommendations. If a good test procedure can be worked out which will bring this subject to conclusion, consideration would be given to make the American Gas and Electric Company system available for such tests. Perhaps a program under the joint auspices of the relay and motor committees would be feasible.

Einar Nilsson (Pacific Gas & Electric Company, San Francisco, Calif.): At our Pittsburgh steam plant one each of the boiler feed pumps, induced draft fans, forced draft fans, and condensate pumps is supplied from a single 2,400-volt bus which is connected during startup to the 2,500-volt tertiary winding of a 110/220-kv system power-interchange transformer. This is the emergency as well as the startup source of the plant. After the machine is synchronized, the station auxiliaries are normally transferred through continuous-circuit or parallel transfer to

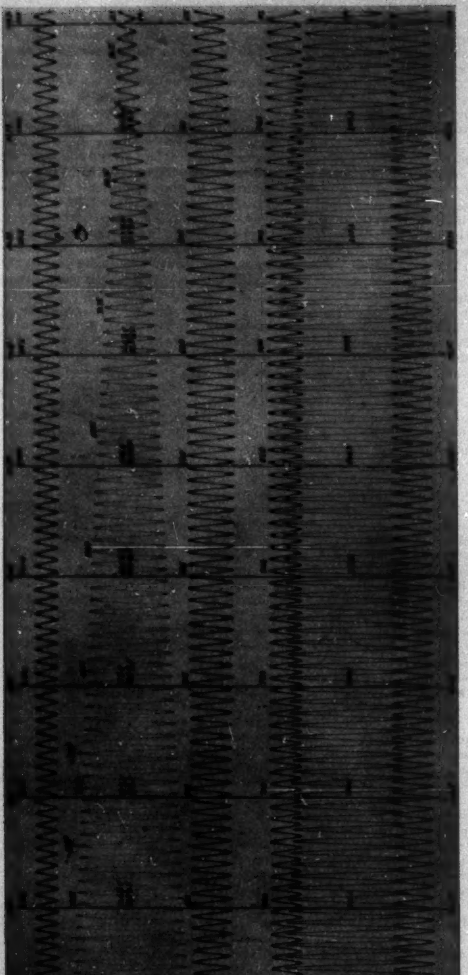

Fig. 7. Test oscillogram traces

A—Boiler feed pump current
B—Motor bus voltage
C—Condensate pump current
D—Induced draft fan current
E—Forced draft fan current
F—Supply bus voltage

the house transformer, which is directly connected to the main generator leads. The parallel transfer will be the normal procedure, delayed interrupted-circuit transfer will be the emergency case. To determine the length of the delay period or dead time required for prevention of excessive motor inrush currents or permitted for uninterrupted boiler operation, a reasonably accurate method is desirable for determining the decay characteristics of the motor voltage. The paper presents such a method. As a check on the method a test performed at Pittsburgh steam plant is being used. The test was set up on a single bus which supplied the motors of one 2,250-horsepower boiler feed pump, one 920-horsepower induced draft fan, one 900-horsepower forced draft fan, and one 500-horsepower condensate pump. Fig. 7 shows the oscillogram obtained for all motors combined. The motor loads during the test were 75 per cent of full load for each of the two pumps, 53 per cent for the induced draft fan, and 33 per cent for the forced draft fan.

In determining some of the motor constants for use in the method shown in the paper, the manufacturer's calculated values were used where available. In the case of the draft fan motors, measured values were obtained from a test of the motors. Fig. 8 shows bus voltage decay by the approximate method plotted for comparison on the same chart as the test values. The chart shows a good agreement between the two.

The author's "Criteria for Successful Bus Transfer" is a concise analysis of the problems involved. For the evaluation and the choice of the transfer method, certain critical characteristics must be known regarding the effect of dead time on boiler operation in general and fuel, feed water, and air in particular. For the benefit of the industry it is hoped that as more experience is gained with automatic transfer of station auxiliary busses, these characteristics will receive wide publicity through professional papers and articles.

C. F. Paulus (The Cleveland Electric Illuminating Company, Cleveland, Ohio): This is an excellent analysis of motor performance during interrupted-circuit transfer conditions. It nicely complements the papers mentioned in the author's references. I agree with the authors statement that in normal starting and stopping operations transfers should be made closed-circuit. I further agree that emergency transfers must be made open-circuit and the spinning motors should not be connected to the new source until their voltage has decayed to a value of 25 per cent of normal or less.

The approach suggested by the authors for calculating the time of decay for a group of motors of varying and various characteristics appears to be somewhat cumbersome and of little value in the design of power plant auxiliary systems. This is because the conditions in a power plant are different than those assumed in this paper. In the modern unitized central station with auxiliaries fed from the generator leads, it is neither necessary nor desirable to transfer all auxiliaries under emergency conditions. This transfer does not take place until the machine has been tripped. When this happens it is better to trip all mills and all but one of the fans. It is best to leave only one feed-water pump on.

At the time the emergency transfer takes place following a tripoff, the unit may have been at full load or at quarter load; the number of auxiliaries running and their loads may vary broadly. Using the author's methods to calculate the voltage decay for all these possible conditions would be a tremendous undertaking and, at best, give data which would not be directly useful. I believe that the problem can be solved by more practical means. The design of the auxiliary system for a power plant can be approached in this fashion.

To make permissible the normal transferring of auxiliaries by the closed-circuit method, transformer reactances should be so specified as to keep circuit-breaker duties within available capabilities. This problem as well as that of staying within available ampere ratings is best accomplished by using two transformers in place of one. For larger units it is generally necessary to provide two boards for each transformer. This arrangement results in four boards which makes it possible to connect only one pump, one fan, and one mill to each board. This makes it possible to transfer the auxiliary loads in four parts.

In closed-circuit transferring, the circulating current is reduced because of the greater reactance in the circuit caused by the split transformer. Failure to transfer successfully is not so serious with only a quarter of the auxiliaries being transferred. Under emergency open-circuit transferring, the inrush from the new source is not so great as to cause a low voltage problem. This inrush is further reduced by transferring only those auxiliaries which should be kept running when the machine has tripped.

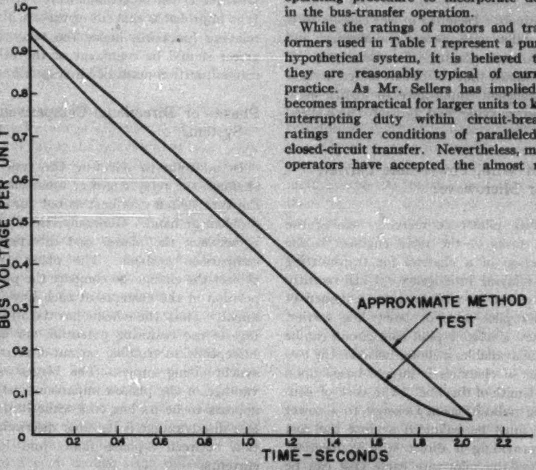

Fig. 8. Bus voltage decay against time

If the transfer to the new source is blocked until the decaying voltage on each bus has reached a value of about 25 per cent there will be no abuse of the motors. The time required to reach this value varies from board to board, and from day to day. The time in itself is of no importance. The voltage which may be fully out of phase is important. In any case, each board will be closed-in to the new source at the earliest permissible time. The likelihood of more than one board being connected to the emergency source simultaneously is very remote. There is no need to calculate the voltage decay for each motor and combination of motors.

D. G. Lewis and W. D. Marsh: We appreciate the interest shown by the several discussers, and are grateful for the many excellent ideas and suggestions presented. With reference to Mr. Mackenzie's remarks, it is certainly true that, where the design of the bus-transfer scheme can be based upon actual tests of the system involved, his is the most satisfactory method. It seems likely, however, that in some cases it will be necessary to have at least an approximate idea of what the system performance will be to select values of transformer impedance and circuit-breaker ratings.

So far as we are aware, there has been only one case of motor-winding failure that could without question be directly traced to the stresses resulting from an excessive number of nondelayed transfers. This involved two 1,500-horsepower boiler feed pump motors subjected to approximately 100 such transfers over a period of 3 or 4 years. The results were quite apparent from visual inspection of the motors which showed distortion of the coil end turns. The winding of one of these motors had failed and, as a result of the investigation, it was decided to change operating procedure to incorporate delay in the bus-transfer operation.

While the ratings of motors and transformers used in Table I represent a purely hypothetical system, it is believed that they are reasonably typical of current practice. As Mr. Sellers has implied, it becomes impractical for larger units to keep interrupting duty within circuit-breaker ratings under conditions of paralleled or closed-circuit transfer. Nevertheless, many operators have accepted the almost negligible risk involved in paralleling sources on the basis that the exposure time is extremely low. There will, of course, be designs wherein normal phase differences will not permit paralleling sources.

Mr. Sellers brings up a very important point in connection with the adequacy of motors under full-voltage starting conditions. Briefly, it should be borne in mind that in considering the ability of electric windings to withstand full-voltage starting we are dealing with a repetitive stress type of phenomenon. Starting duty is merely one of the things that wears out a winding, and a motor may be thought of as having built into it an ability to start a certain number of times before its winding will be worn out. We are not aware of any attempt to designate a specific number of starts as representing normal life for a motor winding. Such a number would vary widely with motor horsepower and speed as well as with conditions of starting voltage and load inertia. But to say that a motor is suitable for full-voltage starting necessarily implies a reasonable number of full-voltage starts. Experience indicates that modern motor windings will have an acceptable life with the number of starts found in normal power plant service. They cannot, however, be expected to have acceptable life under abnormal conditions as typified by, e.g., 30 or 40 starts per day.

The effect of nondelayed transfers is also a repetitive stress problem. However, since the stresses for any one transfer can be much greater than for a single full-voltage start, the life of a winding in terms of number of transfers must be very much shorter. Undoubtedly, the more rapid decay shown in Fig. 1 as compared to the tests conducted by Mr. Sellers is partially the result of the assumption that the motors were operating at name-plate rating.

Mr. Barnes and Mr. Horowitz have brought forth a number of interesting comments. With reference to the nature of winding stress as indicated in the foregoing, one of the more important effects is that of the bending stresses on the end turns of the winding. There are also compressive stresses existing primarily in that portion of the winding in the stator slots.

The statement that the chance of motor damage from transfer is increasing because of increased use of automatic transfer as a lazy means of shutdown may or may not be valid in any particular instance. It is quite obvious that, whether the automatic transfer relaying operates as a result of faults or not, it will be desirable to make periodic tests of the equipment. Usual practice appears to be to test generating station protective relays at intervals of from 6 months to 1 year. While it may be convenient to test the automatic transfer relays each time a unit is shut down, it is apparent that, in the case of a generator shut down once a day, this will result in from 180 to 365 times as much wear and tear on the motors. If a delayed-transfer scheme is used, this duty is drastically reduced.

There are several factors, as pointed out, that tend to reduce the inrush current on transfer below the theoretical maximum. A fault to which the motor could contribute short-circuit current would increase the rate of residual voltage decay; but in the large majority of generators which have high-resistance grounding, there would be no such contribution for a ground fault. The angle at which the reserve source is closed is, of course, a matter of probability, with a certainty that over a large enough number of transfers some will be at an unfavorable angle. The rated closing time of many circuit breakers used in auxiliary systems is 20 cycles, which from Fig. 1 would indicate a decay to more nearly 70-per-cent residual voltage. Actually, breakers of this type very frequently operate in 10 to 15 cycles, giving 80 per cent under the conditions of Fig. 1. However, this is of little significance for practical consideration since the residual voltage decay characteristics of systems vary widely depending on size of motors involved and the load at any particular time. In a similar manner, no general statement can be made as to the phase difference between residual and reserve source voltages at 20 cycles or any other time after tripping.

Relative to the question of auxiliary system loads, at the time of a normal shutdown, the fact that these loads are low is an additional factor favoring delayed transfer since boiler operation should be less critical under these conditions. Source impedance will, of course, tend to reduce motor inrush during transfer, but it is more typically one-third of the load impedance rather than equal to it as Mr. Barnes and Mr. Horowitz have chosen for their example. This would result in 1.5 per-unit voltage on the motors instead of 1.0 per-unit voltage.

It is interesting to know that in some cases it has been necessary to increase instantaneous relay settings to avoid tripping during nondelayed transfer. This would seem to be a sure indication that excessive inrush currents do exist.

Mr. Barnes and Mr. Horowitz's opinion that tripping of the motor during transfer is of little consequence is difficult to reconcile with their opening statement that it is desirable to establish auxiliary power from a reserve source quickly to insure safe shutdown. They suggest that instantaneous relaying may be a means of limiting the damaging effects of instantaneous throw over. Much of the damage has been done in the 5- or 6-cycle clearing time that would be involved but, in any case, if one is willing to accept tripping during a throw over, it would seem to defeat the entire purpose of automatic transfer. Our company has had no experience with shaft failure resulting from bus transfer.

We wish to express our appreciation to Mr. Nilsson for making available the results of his bus-transfer tests and the data showing comparison with the method of calculation presented in the paper.

Mr. Paulus' comments are particularly interesting in that they represent a different approach to the problem. Certainly Mr. Paulus' arrangement of auxiliary power system and his philosophy regarding transfer result in a very high degree of simplicity and reliability, both from the standpoint of design and operation. If it can be assumed, or known from experience, that the times involved for voltage decay to 25 per cent of normal will not be embarrassing to the boiler, there is no need to make any calculations beforehand. If desired, however, the method of the paper is flexible enough to take account of the fact that not all motors are transferred, and it should be possible to make the calculation only once or twice for the expected conditions involving the longest delays. Admittedly, if everyone were willing to shut down a generating unit under every condition for which emergency transfer is required, there would be much less need to know or be able to predict the voltage decay and recovery characteristics of auxiliary motor systems.

Line and Transformer Bank Relaying Systems

J. L. BLACKBURN

G. D. ROCKEFELLER
ASSOCIATE MEMBER AIEE

IN MANY power systems, connections of transmission lines and transformer banks are often encountered which require special consideration for adequate relay protection. Though these arrangements may raise difficult relaying problems, the overriding factor is the appreciable economic advantages which result. The problems can be grouped into two general classes: the 3-terminal lines, and the termination of a transmission line in a transformer bank. In this paper various cases frequently encountered together with solutions to the relaying problem are presented.

The discussion will be generally limited to relaying systems, which provide high-speed simultaneous tripping of all line terminals. Included in this classification are pilot wire, power-line carrier, and microwave relaying. In other words, it is assumed that the circuit under study is of sufficient importance to justify high-speed relaying and possibly high-speed reclosing.

Pilot Wire, Power-Line Carrier, or Microwave?

With pilot-type relaying, one of the first tasks of the relay engineer is the selection of a channel for transmitting the relaying intelligence. Until recently the choice of a channel was confined to either pilot wire or power-line carrier. Where a reliable pilot-wire circuit can be made available, a choice between the two types of channels is largely based upon the length of the line. The cost of coupling radio-frequency energy to a power line must be balanced against the cost of providing a direct wire connection. Unless the pilot-wire cable cost can be shared by other functions, a length on the order of 7 to 10 miles represents the economic limit. However, wire circuits in excess of 20 miles are in use in this country.[1]

At present, microwave is limited to key areas of the system where many functions can ride the microwave circuit. Where ten or more channels are required between any two points, it is likely that microwave will be economically feasible. It is improbable that all of these will be relaying functions, hence the relay engineer should be cognizant of the other communication needs of his system.[2]

Phase- or Directional-Comparison System?

In addition to selecting the type of channel, the relay engineer must choose the type of relaying best suited for the problem at hand. Generally, the choice is between the phase- and directional-comparison systems. The phase type utilizes the channel to compare the phase position of the currents at each line terminal. Thus, the scheme has the advantage of not requiring potential, nor is it susceptible to tripping on out-of-step or synchronizing surges. The biggest advantage of the phase-comparison system appears to be its low cost while its biggest disadvantage is its poor discrimination between 3-phase faults and load currents.

With the directional-comparison sys-

Paper 55-88, recommended by the AIEE Relays Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 19, 1954; made available for printing November 18, 1954.

tem, the direction of the fault is determined independently at each station and the result transmitted over the channel. Generally, this system is more flexible to system changes and addition of taps. A more detailed comparison of the two systems utilizing a carrier or microwave channel is given in reference 3.

Choosing the Electrical Quantities

A further job of the relay engineer is the selection of the electrical quantities for operating the relays and at what point in the system these quantities should be measured. The decision on where to measure is based on the requirements of the protective system or, if the choice is restricted, compromises may be necessary in the protection. This is one of the areas where system design can appreciably influence protective relaying.

The problems encountered in selecting the quantities are well illustrated where the transmission line terminates in a transformer bank and where either line-side or bus-side current and potential quantities may be used. Sometimes it is best to use bus-side quantities to enable the line protection system to clear bank faults, even though bank differential relays are present. However, bus quantities are not always satisfactory. Bus side zero-sequence current or voltage will not suffice for ground relaying of the line where the bank is connected wye-delta. Also, bus side current may not be satisfactory where the line is terminated in a transformer bank and high-speed reclosing is desired following line faults. If bus side current is used, the line relays are likely to trip for transformer faults and initiate reclosing. Since it is not considered desirable to reclose following a transformer fault, it is necessary to use line side current or to provide a remote trip channel to block reclosing of the remote breaker on transformer faults. To block reclosing, the remote trip signal must be received at the remote station before reclosing can be initiated by the line relays.

In some cases, the remote trip channel may also be used to block reclosing. This feature may obviate the need for blocking line relay tripping on bank faults by the use of line side quantities, if the differential relays can initiate a remote tripping signal before the line relays set up reclosing. Some delay in initiating the reclosing may be necessary to assume positive blocking for transformer faults.

One other illustration of the effect on on the protection of the point of measurement of the electrical quantities applies to the application of distance-type relays. With these relays, line side potential or its equivalent is preferable to bus voltage. This is particularly true where the bank impedance is large in relation to that of the line. Since the instantaneous elements should be set to protect a maximum of 80 to 90 per cent of the total impedance to the remote bus, a large bank impedance will limit line coverage when using bus side voltage. As an example, assume that the impedance of the line is Z and of the bank $2Z$. With the instantaneous element Z_1 set for 85 per cent of the total $3Z$, only 45 per cent of the line is covered. However, the use of bus potential will not compromise the first line protection since the carrier tripping element Z_2 is set to overreach the remote bus.

Two-Terminal Line With Transformer Termination

The electrical quantities which should be utilized for a 2-terminal line with a transformer termination are listed in Fig. 1 for four types of power transformer connections. These are generally the preferred or recommended connections, and it should be recognized that special circumstances may alter them. For each case solutions are given with and without high-speed reclosing for both phase- and directional-comparison systems. In all instances the distance relays at station I receive line voltage or the equivalent, while they use line-side current only for high-speed reclosing applications. At station II, the distance relays are always connected in standard fashion. The station II arrangement for the phase-comparison system can likewise be standard in every instance. Since the phase-comparison system is susceptible to tripping on magnetizing inrush current, a suppressor should be used where the bank is in the protective zone. The trip suppressor can be eliminated by using line-side currents but then, as suggested previously, remote tripping equipment is necessary in order to clear transformer faults at station II. Some of the special considerations are detailed in the following.

Case A

Where a delta-way bank is used with the ground on the line side, the ground relay in the directional-comparison scheme may be nondirectional at station I of Fig. 1, if bank fault tripping can be tolerated. For phase comparison the low-side current transformers at station I are connected in delta. Sensitive ground fault protection is attained by using bank neutral current at station I and comparing it with residual current at station II via the channel.

Where microwave or pilot wire is used, the channel could be employed for transfer tripping. A single impedance element per phase and a directional ground relay at station II could be set to look into the bank and clear both circuit breakers at high speed for all line faults. The relays trip the station II circuit breaker direct and the station I breaker by remote tripping. Where high-speed reclosing is desired, this system is not adequate since line relay tripping will occur on some bank faults.

Case B

Where the delta-wye bank is grounded on the bus side, special ground relay arrangements for the directional-comparison system are utilized, as shown in Fig. 2. The trip elements are energized with residual voltage and residual current respectively at stations I and II, while the reverse is true for the start or blocking elements.

When a line-to-ground fault occurs in the line section, the *CSG* element is picked up by $3E_0$ at station I and by $3I_0$ at station II. At both stations, the *CSG* contact opens to stop any possible transmission of a blocking signal and also removes the short circuit from the *RRT* coil. Since no blocking current is flowing in the holding coil *RRH*, the tripping current in the *RRT* coil causes the carrier relay contact *RRG* to close, permitting the $3E_0$ and $3I_0$ elements at stations I and II respectively to trip the breakers.

The $3I_0$ element at station I is required only if it is desired to segregate line tripping from bank tripping for reclosing purposes. Then, for faults in the bank at station I, the $3I_0$ as well as the $3E_0$ element picks up at station I. The $3I_0$ element takes preference, because of the *CSO* element, and starts transmission of a blocking signal as well as short-circuiting the *RRT* coil to prevent local tripping. The blocking signal produces holding current in the *RRH* coil at station II. This current prevents tripping even though the *RRT* coil is energized.

If the fault is beyond station II, the $3E_0$ element starts transmission at station II to block the $3E_0$ trip at station I. For this fault, no zero-sequence current is present in either circuit breaker.

Case C

Where a wye-wye-delta tertiary bank is used, the phase-comparison connections are of interest. A standard system is utilized for high-speed reclosing, but where the bank is included in the line protective zone the connections should be made as shown in Fig. 3.

The *HCB* pilot wire relay of Fig. 3 employs a composite filter whose single-phase output voltage is a function of both positive- and zero-sequence current. The open-circuit filter voltage for this special connection, but without the 3/1 I_{A0} current transformer, is

$$E_F = 2I_{A1}R_1 + I_{A0}R_1 + I_{A0N}R_0 \qquad (1)$$

Where no zero-sequence source is present within the protective zone, the filter output voltage is the same at both stations for an external fault. However, in this particular case, the neutral current at station I produces an $I_{A0N}R_0$ voltage, while the same current flowing to an external fault would normally produce at station II not only the balancing $I_{A0N}R_0$ voltage but a spurious $I_{A0}R_1$ potential as well. In Fig. 3, this latter response is eliminated by shunting I_{A0} around the R_1 resistor by means of the I_{A0} current transformer. By this means the filter response is modified and the open-circuit filter voltage becomes

$$E_F = 2I_{A1}R_1 + I_{A0N}R_0 \qquad (2)$$

By inserting the net bank neutral current into the station I filter, an equal response is obtained at both stations regardless of the current distribution, provided that

$$\frac{V_{II}}{V_I} = \left(\frac{\text{ratio I}}{\text{ratio II}}\right)\left(\frac{R_1\,(\text{II})}{R_1\,(\text{I})}\right) = \left(\frac{\text{ratio I}}{\text{ratio II}}\right)\left(\frac{R_0\,(\text{II})}{R_0\,(\text{I})}\right) \qquad (3)$$

where R_1 and R_0 are the tap values of the filter resistors, and V is the system voltage. Equation 3 states that the filter responses can be equalized either by proportioning the current-transformer ratios or the filter resistor taps, or a combination of both.

The current transformer connections in Fig. 3 apply equally well for *HKB* carrier relays. The *HKB* filter responds to both positive- and negative-sequence current as well as to zero-sequence current. The open-circuit voltage for this connection, but without the I_{A0} current transformer, is

$$E_F = K_1I_{A1} + K_2I_{A2} + I_{A0}R_1 + I_{A0N} + R_0 \qquad (4)$$

where K_1 and K_2 are constants whose values vary with settings. A comparison of equations 4 and 1 shows that the zero-sequence responses are the same in both relays. Therefore, the I_{A0} current transformer may again be used to modify the filter voltage as

$$E_F = K_1I_{A1} + K_2I_{A2} + I_{A0N}R_0 \qquad (5)$$

While an actual magnitude comparison is not made with the carrier scheme, the filter responses should be very nearly the same to insure proper time co-ordination between the start and trip fault detectors of the *HKB*. The I_{A0} current transformer should, thus, be utilized unless the spurious $I_{A0}R_1$ response is of negligible magnitude.

CASE D

The use of an autotransformer necessitates additional consideration not present with the wye-wye-delta bank of case *C*. Where the phase-comparison scheme includes the bank, the connections will be the same as in Fig. 3 except that the current-transformer ratios and filter resistor taps should be proportioned as follows

$$\left(\frac{R_1\,(\text{II})}{R_1\,(\text{I})}\right)\left(\frac{\text{ratio I}}{\text{ratio II}}\right) = \frac{V_{II}}{V_I} \qquad (6)$$

$$\frac{R_0\,(\text{II})}{R_0\,(\text{I})} = \frac{\text{ratio I}}{\text{ratio II}} \qquad (7)$$

The ratio of the neutral current-transformer should match the ratio of the local line current transformers. With this arrangement, the R_0 settings are not a function of the power-transformer voltage ratio.

If tertiary current is used instead of neutral current, the current-transformer ratios should be

$$\frac{V_I}{V_T} = \frac{\text{ratio } T}{\text{ratio I}} \qquad (8)$$

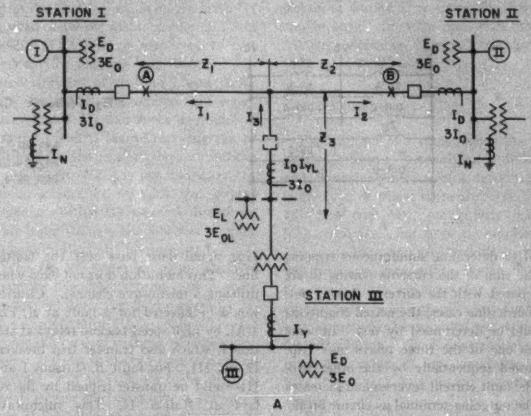
where V_T and ratio T are the voltage and current-transformer ratio of the tertiary respectively.

Three-Terminal Lines

All too frequently a 3-terminal line presents the relay engineer with difficult protection problems. This is particularly true where high-speed simultaneous tripping of all circuit breakers is required for high-speed reclosing.

One of the difficulties which occurs often is the reversal of current through station III for faults *A* or *B* of Fig. 4(A). Even though the fault is in the protective zone, the I_3 current may flow out of the line and to the fault via a tie line (not shown) between stations II and III for fault *B*.

The phase-comparison pilot wire system *HCB* offers the only possibility of simultaneously tripping all three circuit breakers under these conditions, but this is possible only if the current flowing out of one terminal is small compared to the total flowing in the other two. As a good approximation, the published characteristic curves for 2-terminal lines can be



CASE	STATION III CONNECTIONS	TRIP ON BANK FAULT	STATIONS I & II			STATION III			
			PHASE	GROUND		PHASE		GROUND	
				START	TRIP	START	TRIP	START	TRIP
A		NO	E_D & I_D (Z)	$3I_0$	$3I_0+I_N$ OR $3E_0$ (DIR)	E_L & I_D (HZ-3)	E_L & I_{YL} (H3)	$3I_0$	$3I_0+I_N$ OR $3E_{OL}$ (DIR)
		YES	E_D & I_D (Z)	$3I_0$	$3I_0+I_N$ OR $3E_0$ (DIR)	—	E_D & I_Y (H3)	—	I_N

used to determine simultaneous tripping if the sum of the currents flowing in are compared with the currents flowing out. In borderline cases, the actual conditions should be determined by test. In some cases one of the three relays may trip, followed sequentially by the other two, as the fault current reverses and increases in the outgoing terminal as circuit breakers open. This pilot-wire system is applicable to 3-terminal lines where the pilot-wire resistance is below 500 ohms per leg and the shunt capacitance is below 0.60 microfarad per leg.

With directional-comparison or phase-comparison carrier schemes, simultaneous tripping is not possible. If the I_3 current for the case of reverse at station III is sufficiently large to operate the carrier start elements, carrier tripping will be prevented at all line terminals. If the current reversal at station III is too small to operate the start elements, circuit breakers I and II will be tripped by the carrier relays while breaker III will clear sequentially.

However, high-speed simultaneous clearing is possible with transfer tripping where I_3 reversal occurs. A transfer trip system with a power-line carrier channel is not considered feasible since the tripping signal must pass over the faulted line. This limitation does not exist when utilizing a microwave channel. Clearing would be effected for a fault at *A*, Fig. 4(A), by high-speed backup relays at station I, which also transfer trip breakers II and III. For fault *B*, stations I and III would be transfer-tripped by the relays at station II. This microwave scheme is possible because the reversal at station III occurs only for fault *A* near station I or for fault *B* near station II up to, but not at, the tap point. Thus, in most cases, instantaneous phase distance and instantaneous ground overcurrent relays can be applied without overreaching the remote stations.

Phase-comparison carrier is not widely applicable to 3-terminal lines, since the ratio of minimum 3-phase fault current through any line terminal to the maximum load current through the same terminal must be at least 3.33.[4] However, a modified 2-terminal system may be used, where the current contribution of station III is too small to pick up the fault detectors at stations I and II for a fault beyond one of these latter stations. Where there is negligible backfeed, a blocking terminal is applied at station III if slow-speed clearing of circuit breaker III is tolerable. Overcurrent relays at station III pick up for local external faults and key carrier to block tripping of stations I and II.

Another difficulty on 3-terminal lines is frequently present when applying a directional-comparison scheme to the line of Fig. 4(A). Distance elements at station III (current flowing in) do not encounter the actual impedance Z_3+Z_1 for fault *A*. Instead they see

$$Z_{\text{apparent}}=Z_3+Z_1(I_1/I_3)=Z_3+Z_1+Z_1\times(-I_2/I_3) \quad (9)$$

and similarly for fault *B*

$$Z_{\text{apparent}}=Z_3+Z_2(I_2/I_3)=Z_3+Z_2+Z_2\times(-I_1/I_3) \quad (10)$$

The minus sign on I_1 and I_2 indicates the current flows in the direction opposite from that shown in Fig. 4(A) for the faults involved.

This additional impedance is caused by the voltage drop produced by infeed current, or current not measured by the relays at station III. This distance-element underreach increases as the current contribution of station III becomes proportionately smaller. Where I_3 is very small compared to I_1 or I_2, it is not possible to set the zone-2 impedance elements to reach the station I and II busses.

When I_3 becomes too small for proper

distance-element reach, there is no need to clear breaker III from the standpoint of system stability. However, a very small current will maintain a fault arc so that, where high-speed reclosing of I and II is required, circuit breaker III must be cleared simultaneously with I and II to effect extinguishing of the arc before reclosing.

The breaker III reach may be extended by the use of the instantaneous voltage elements, whose contacts are connected in series with the directional-element contacts of the distance relays. Fig. 5 shows the simplified connections for this system. When a phase fault occurs on the line but is beyond the reach of the zone-2 distance elements, tripping can be effected when one of the voltage elements *SV* drops out. The closing of *DIR* and *SV* causes the *CSP* element to be energized. The *CSP* contact in Fig. 5(B) removes the short circuit on the tripping coil *RRT* of the receiver relay. Since the holding coil *RRH* of this receiver relay is not energized by a blocking signal from station I or II, the *RRT* coil current closes the receiver relay contact *RRP* in Fig. 5(A). Tripping of the circuit breaker then occurs through *DIR*, *SV*, and *RRP*.

The *SV* distance-element system would be applicable where the dashed bus of Fig. 4(A) is present. The line-side bus would only exist when an additional tie line is connected to station III. A set of 3-zone distance relays could then be justified on the basis that a large I_3 is available when this tie is in service. The *SV* elements are of value when this tie line is open and I_3 is supplied only by the transformer bank. For correct operation of the scheme on faults beyond stations I and II, the carrier start elements at stations I and II must operate for all faults seen by the *SV* and Z_2 elements at station III.

The relaying considerations can be quite different where the dashed circuit breaker and bus at station III of Fig. 4(A) are not present. With the line terminated in a transformer bank, the fault current source III is frequently nonexistent or very small in comparison to sources I and II. Distance-relay underreach caused by current infeed is likely to be serious. Where high-speed simultaneous tripping is required, the following two solutions are considered, utilizing directional-comparison carrier relaying.

Case A

In Fig. 4(B), the electrical quantities are listed for the case of a wye-delta bank at III, with the line side grounded and no high side breaker. The connections of stations I and II are standard. However, for phase tripping at station III, a polyphase directional relay *H*3 is utilized in conjunction with instantaneous voltage elements. The d-c circuits for this system are shown in Fig. 6. Carrier tripping occurs through the *H*3, *SV*, and *RRP* contacts. The *RRP* contact is the supervising feature of the circuit, since it will remain open if a carrier signal is received from either station I or II. Stations I and II, in turn are supervised by station III. The blocking signal from station III is initiated by the distance relay *HZ*-3 in Fig. 6. This relay is employed to prevent carrier tripping and, hence, high-speed reclosing of stations I and II for bank faults. If the remote trip signal from station III can block reclosing of stations I and II before reclosing can be initiated by the carrier relays at stations I and II, the *HZ*-3 is not necessary. A similar choice exists with the ground relays at station III where a directional relay is needed only when carrier tripping on bank faults must be prevented.

The *H3-SV* system is more sensitive than the standard scheme and is more economical than the 3-zone distance relays where source III is small. The *H*3 should not be used without voltage supervision, since it is likely to operate for an external fault too remote to be seen by the Z_3 carrier start elements at stations I and II. Should the start elements at stations I and II fail to operate, incorrect tripping of circuit breaker III will occur if voltage supervision is not used. The Z_3 settings should be made so that all external faults which cause *SV* dropout also result in the Z_3 operation.

Case B

Fig. 4(B) also lists the electrical quantities to be used with a wye-delta bank at station III when the bus side winding is grounded and there is no high side circuit breaker. The phase fault protection is the same as that of case *A*, but special consideration is necessary on the ground fault system. Since no zero-sequence current is available at station III for a line fault, carrier-supervised tripping must be effected with a voltage element $3E_{0L}$.

If the fault is internal, the directional elements in conjunction with overcurrent elements will stop carrier transmission at stations I and II so that the $3E_{0L}$ element at station III can clear the fault. If the fault is external and beyond station I, an overcurrent element at station I will operate to start carrier and block tripping of stations II and III. The $3E_0$ elements can also start carrier at stations I and II. For the fault beyond station I, the current contribution from station II may be below the overcurrent start-element pickup at station I, or circuit breaker II may be open. In either case, without the $3E_0$ start elements, incorrect tripping of station III would occur.

Conclusions

The solution of a transmission-line relaying problem is generally more difficult and expensive where a bank termination is involved or where there are more than two line terminals, particularly where high-speed reclosing is to be employed. Minor modifications to standard systems will in some cases suffice, while instantaneous voltage elements for phase or ground tripping or a transfer trip channel may sometimes be required for a satisfactory solution. The most commonly encountered problems are catalogued in Figs. 1 and 4 as a guide for convenient reference.

◆

Discussion

H. P. Bruncke (Northern States Power Company, Minneapolis, Minn.): The authors are to be commended for their paper and for the way in which they have outlined the various phases of the problem suggested in the title. The tabulation of types of relays for certain conditions is also very helpful.

I would like to comment on the authors' comparison between the phase- and directional-comparison relay systems. It was stated that the biggest advantage of the phase-comparison system appears to be its low cost. This is true if the protection engineer will be satisfied with just the so-called first-zone operation. In the event that backup protection is required, then the cost of the phase-comparison system will increase sharply. The phase-comparison system, of course, has the advantage that it does not require potential trans-

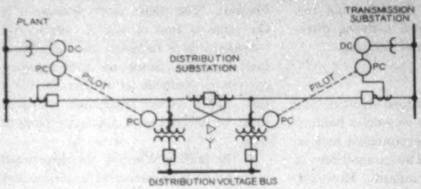

Fig. 7. Relay scheme for a transmission line with a distribution substation tapped on

DC — Directional-comparison relays
PC — Phase-comparison relays

formers. On the basis of this fact a relay scheme incorporating both the phase-comparison and the directional-comparison relays is suggested.

The authors have grouped the problems into two classes: 3-terminal lines and lines terminating in a transformer. I would like to suggest a third class, i.e., a transmission line tapped by a distribution substation. The combination relay scheme can be used for this third class. In Fig. 7 this scheme is used on a transmission line with circuit breakers at each end and with a distribution substation in the line. The distribution substation consists of two transformer banks connected to the line through air-break switches with a circuit breaker between the connection. The low side of the banks is provided with circuit breakers which will be connected to a solid distribution voltage bus. The directional-comparison relays are provided for the circuit breakers at each end of the transmission line. These will not be the carrier-current pilot type. The phase-comparison relays will be provided between the tie circuit breaker at the distribution substation and the circuit breaker at each end of the line. The relays at the distribution substation will be energized by parallel connection of the current transformers in the circuit breaker and in the high side of the transformer bank. The relays will be provided with a carrier-current pilot; thus the overall picture will be first-zone operation for each section when the phase-comparison relays are in operation and backup protection in the event that the phase-comparison relaying is out of service. The directional-comparison relays will then protect the system for faults on the transmission lines.

The authors mentioned that "system design can appreciably influence protective relaying." I believe that quite a few relay engineers have experienced the fact that usually the transmission system is laid out, and about the time the line is to be built or connections are to be made the relay engineer is consulted regarding how it can be protected. I concur with the authors that system designs should be influenced by the type of protective relaying which is available.

I agree with the authors that in the case of failures of transformer banks it is not desirable to reclose either the line or the bank; of course, with remote trip either by carrier or other means this can be accomplished very easily. Mr. Blackburn and Mr. Rockefeller mentioned that transfer trip schemes with power-line carrier channel are not considered feasible since the tripping signal must pass over the faulted line. It is agreed that there is a possibility that the signal may not reach the other end of the line; however, the chances are that a line fault will not occur at the same time that the transformer fault occurs. In all cases where transfer trip is used with power-line carrier it has been a practice to install a wave trap between the line and the transformer terminals to eliminate just such a condition as the authors refer to.

J. R. Linders (Cleveland Electric Illuminating Company, Cleveland, Ohio): The authors have presented a very worth-while and timely subject. The combined protective relay problems of transformer protection, no high-side transformer breaker, multiterminal transmission circuits, and high-speed clearing and reclosing requirements can only be solved by the complete assimilation of papers such as this. When one considers modern-day equipment reliability with its reduced maintenance requirements plus the precise knowledge of system performance gained from a-c network analyzer studies, the complex power circuits described in this paper are certain to become commonplace in the near future. I personally believe the relay engineer will be fortunate if his problems stay as simple as presented here.

It would therefore be appropriate if more background could be provided on some of the points touched on in this paper. For example, the development of equation 2 could be expanded in the author's closure or additional references provided.

In order to satisfy equation 8, the current transformer in the tertiary of a large autotransformer which we are now installing on our system would have required a ratio of 20,000 to 5. Since we have had no experience with anything near this ratio we were forced to develop an alternate solution using a directional-comparison method. It is quite possible that the contribution from this winding could have been entirely ignored, but we did not have the time to develop the significance of doing this. The relay application engineer must fully understand the principles behind relationships of all of these equations if he is to avoid pitfalls.

I believe there are additional considerations to the use of neutral currents, from autotransformers and would suggest an additional reference.[1]

The more complete solution to the 3-terminal line problem by means of transfer trip via microwave as contrasted to a carrier scheme fits in with our own plans. Since experience with this new medium is extremely limited, we believe it is essential to provide some type of fault detector to supervise the trip signal. In the case cited of the outfeed from the third terminal, a conventional fault detector responsive to conditions at this third terminal is not possible. We therefore plan on permitting tripping at station III for faults near station I or station II only when the second-zone indication from the second station as well as first-zone indication from the first station are received simultaneously at station III. Since these signals will arrive over completely separate microwave facilities, the possibility of a false tripout from any cause (including testing!) is very remote. Only experience will tell if the reliability is adversely effected by requiring two separate systems to respond properly to provide a trip signal.

The transfer trip signal originating from a transformer protective relay operation likewise cannot have the security of a local fault detector at the receiving terminal. In this case we are planning on permitting the tripping upon the reception of a single transfer trip signal. However, we plan on then immediately inspecting the line for 3-phase potential. If this exists, the trip signal was false and the breaker will be immediately reclosed, and the transfer trip equipment locked out. Since our system must obviously be set up to handle a tripout and reclosure no harm will be done. There are obviously other facets to these problems and several relay communication channels will be required to do the entire relaying job.

In conclusion I would like to return to my opening thought on the complexities of future power systems and suggest that we can simplify one area of thought communication by using standard terminology and function numbers where applicable rather than manufacturers' specific type or model designation.

REFERENCE

1. GROUND RELAYING POLARIZATION, J. L. Blackburn. *AIEE Transactions*, vol. 71, pt. III, Dec. 1952, pp. 1088–95.

Charles Morrison and **M. A. Jansen** (The Potomac Edison Company, Hagerstown, Md.): The authors have presented effectively and concisely an outline of the problems associated with the protection of 3-terminal lines and lines with transformer termination. In this connection some of our company's experience may be of interest.

Power-line carrier is used exclusively as the channel for all pilot-type relaying because we believe this type of channel is less susceptible to extraneous influence than any of the other types available. For reasons that will be amplified later phase-comparison relaying is now limited to 2-terminal metallic circuits, all relatively short. For general application, including 3-terminal lines and lines with transformer termination, we are using directional-comparison relays having modified impedance characteristics. Our experience justifies a continuation of this policy as to both relays and relaying channels.

Our first application of phase-comparison relays was made on a 3-terminal line, two terminals of which included transformers. Referring to Fig. 4, one of these was a case-A and the other a case-B terminal. Bus side currents were used in both cases, and high-speed reclosing was installed at all terminals, but was not particularly successful. Tests indicated that this was brought about partly by transformer magnetizing inrush current, actually by the difference in inrush current per phase when the case-A transformer was re-energized from the terminal at station I. Tests indicated that by desensitizing the phase-comparison relay at station I with respect to zero-phase sequence current this difficulty would be eliminated. However, in this particular situation delayed tripping was less acceptable than delayed reclosing, so this expedient was not adopted for regular operation.

Incidental to these tests we noted some delay in the reset time of the phase-comparison relays and some unaccounted-for phase-angle differences between local electrical quantities and those received from remote terminals for through faults. The first difficulty was corrected by internal changes in the relays, but before the second could be rationalized the needs of the system made it necessary to break the circuit apart as far as relaying was concerned. However, for these and other reasons we had decided by this time to use directional-comparison relaying on most of our high-voltage transmission system, and some had already been installed. Phase-comparison relaying was restricted to short 2-terminal lines without transformer termination; in fact, for this purpose phase-comparison relaying is unique, and additional terminals have been installed by us for that reason.

In addition to the two types of carrier pilot relaying in general use on our system, we have three remote trip schemes operating over frequency-shift carrier channels. These are all special applications used in connection with lines having transformer termination. Since the circumstances and equipment differ in each case these will be described individually.

CASE 1

This is a 3-terminal application having one transformer termination similar to case B, Fig. 4. The relaying quantities used for line faults are those taken from the line side of the transformer at station III. Since the line relays do not initiate tripping of any breakers for a transformer fault, high-speed reclosing is not blocked by operation of the line relays. The transformer at station III is protected from internal faults by variable percentage differential relays, which initiate tripping of the local breaker on the bus side of the transformer and block its reclosing. The differential relays at station III also function to set up the remote trip signal to stations I and II over the frequency-shift channel. Since this line is of primary importance to the power system and we had no previous experience with frequency-shift equipment, we interlocked the trip circuit of this scheme at stations I and II with the blocking circuit of the carrier pilot relays which protect the line between stations I, II, and III. The performance of this combined relaying system is as follows:

a. For a line fault the directional-comparison relays at all stations operate in the usual manner. Breakers at stations I, II, and III trip and reclose.

b. For a transformer fault the differential relays at station III operate to trip the local breaker and block its reclosing. They also initiate the transfer trip signal to stations I and II. At the same time station III line relays transmit a blocking signal to the line relays at stations I and II. The receipt of both signals at stations I and II set up the trip circuit to trip the line breakers and block their reclosing.

CASE 2

This is also a 3-terminal line having a transformer termination similar to case 1; however, the circuit itself is not considered as important as that described in case 1. At station III the quantity $3E_{0L}$ is used for ground relaying, but for the phase relays bus side quantities E_D and I_Y are used. The line and transformer are thus protected as a unit, the transformer impedance being relatively large. Although at station III this limits the line coverage of the instantaneous elements, at stations I and II it permits setting them into the transformer for full line coverage. In addition to this over-all protection, the transformer will in the near future be equipped with a rate-of-pressure-rise device which will function as a relay to trip the local breaker at station III, and, by means of a remote trip channel, the breakers at stations I and II. No interlocking signal is planned for this circuit. Breaker reclosing will be blocked when their tripping is initiated by the transformer pressure-rise device.

CASE 3

This is a 2-terminal line having an autotransformer at one terminal similar to case D, Fig. 1. However, the autotransformer at station I has both line and bus side breakers and is protected by variable percentage differential relays which trip the two breakers in case of a fault between them. Because the autotransformer is in itself a source of zero-phase sequence current to the system, I_D and I_{DL} are used for the differential relays. Over-all protection for the line and transformer is provided by time-delay overcurrent relays at station I and distance relays with instantaneous elements at station II. The transformer impedance is again relatively large and the instantaneous elements at station II can be set into the transformer impedance for full line coverage. This fact is used to advantage and by means of a remote trip frequency-shift channel nondelayed tripping is transferred to the bus side breaker at station I for the usual line faults. The bus side breaker is used to clear line faults in order to limit the duty on the line side breaker to the clearing of transformer faults beyond the reach of the instantaneous relay elements at station II.

These three applications illustrate the adaptations which may be made in the protection of a transformer as part of a line terminal. They further illustrate the use of electrical quantities suggested by the authors in Figs. 1 and 4. In connection with case D, Fig. 1, we make a qualifying comment with reference to the quantities suitable for ground-relay polarization at station I. Neither I_N nor I_T can be used indiscriminately for ground-relay polarization when supplied from an autotransformer. We realize that Mr. Blackburn has previously presented the reasons why these quantities are not satisfactory under all conditions (see ref. 1 of Mr. Linder's discussion) but we believe this should be referred to in this paper.

The authors' suggestions for correcting the underreach of distance relay elements due to current infeed on 3-terminal lines are all of considerable interest. One of these, illustrated in Fig. 5, may have an application for us, where in one instance this problem was particularly troublesome.

G. W. Hampe (Commonwealth Edison Company, Chicago, Ill.): The authors are to be congratulated on their courage and industry in tackling the grueling job of setting up preferred connections for the cases likely to be encountered in the field. With these fairly well established, I would like to discuss what to do next. The authors discussed automatic reclosures and special adaptations such as blocking automatic reclosure when transformer faults are indicated.

One trouble with the present type of automatic reclosing is that it was developed for one particular type of high-voltage system, namely a pure transmission system. In such a system there are only one or two system ties, and reclosure must be made at high speed, or the two ends of the system have lost synchronism. Many present systems, including that of my company, are dual purpose, i.e., for transmission combined with distribution. The Northern Illinois area, including Chicago, is solidly interconnected with 138-kv lines. The quick removal of one 138-kv line could cause loss of synchronism only under very special circumstances. The lines remote from the metropolitan area may have three to five terminals, some with no breakers on transformer taps. Some have single-phase 138-kv grounding switches to cause remote tripping for transformer protection. Only a few of the lines can profitably use high-speed reclosing.

The lines are generally well shielded with static wires and tower-footing resistance is fairly low. Hence in the few cases when lightning does strike it is vicious and the strokes tend to be repetitive. I pointed out in another discussion[1] that the effectiveness of conventional reclosing equipment has been low. It seems that the sustained and repetitive faults were (and will be) about 30 per cent of the total, not counting the grounding switch operations. Thus it seems that we should do some further pioneering on the subject of reclosing. Consider the following suggestions:

1. There should be no distinction in the manner of tripping. That is, reclosure could occur whether the line tripped from carrier pilot, ground instantaneous, distance (all zones), or ground backup.

2. On any trip as in item 1, the local directional- or phase-comparison carrier transmission should be turned off and held off while the local breaker opens and about 15 cycles thereafter. At the end of this period carrier control would be returned to the conventional carrier start-and-stop elements.

3. On lines requiring reclosing with speed, a carrier receiver relay should suspend reclosure until incoming signals stop, after which it is to be completed without further delay.

4. On lines not requiring speed, voltages taken from line connected potential transformers or devices should be used to determine when the line is de-energized. After it registers as de-energized, reclosure is to be completed.

5. Arrangements should be made for reclosure of a line on a sound, balanced backfeed. This could be used on all lines, but particularly on multiterminal lines. To detect the sound backfeed a relay which closes on positive-sequence line voltage V_1 or on $V_1 - V_0$ could be used.

6. On lines where automatic grounding switches are used, and possibly other multiterminal lines, use item 4 at only one terminal and item 5 at all the others. The terminal with item 4 would probably be one of low fault current capability. If it closed, and did not retrip, the major and other minor terminals would then follow by item 5. With such functions, the need for blocking reclosing by closely co-ordinated remote trip channels is considerably reduced. Remote trip channels may still be needed where high-speed reclosing is desired.

These suggestions do not exhaust the possible combinations. For reasonable effectiveness of automatic reclosing on high-voltage transmission-distribution grids automation along the lines of the foregoing seems to be needed.

J. L. Blackburn and G. D. Rockefeller: The discussers valuable contributions to this paper are appreciated.

With reference to Mr. Bruncke's discussion, the comparison between phase- and directional-comparison systems did not include any backup protection. A more complete discussion of this is given in reference 3 of the paper. It also happens that many applications of phase-comparison relays are made using distance-type relays for phase backup protection. Even with this complement, the cost is essentially the same as an all-directional comparison scheme. One further advantage of the phase-comparison system was brought out by Mr. Morrison and Mr. Jansen. This is the independence of the phase-comparison scheme to fault voltage which makes it particularly advantageous for very short lines. The third class of protected line suggested by Mr. Bruncke is an interesting variation of the normal 2-terminal line problem.

The last paragraph of Mr. Bruncke's discussion gives us an opportunity to clarify our nomenclature with respect to remote and transfer trip. While not a national standard, the authors have been using the term "remote trip" to signify the tripping of a remote breaker following selected relay operations, such as transformer differential relays, while "transfer trip" signifies the tripping of a remote breaker following the operation of all the protective relays at a local location. In this paper only transfer trip schemes have been outlined. We generally do not consider transfer tripping over carrier acceptable for clearing line faults because of the possibility of the fault short-circuiting or limiting the desired carrier signal. However, it has been used for phase faults where adequate ground-fault protection was obtained through a conventional carrier scheme. Remote tripping as used here refers to the clearing of the remote breaker following a transformer fault.

Mr. Linders requests that equation 2 of the paper be explained. This equation was derived from equation 1, which is the filter response of a standard connected pilot-wire relay. By comparing the two equations it is seen that the $I_{A0}R_1$ term of equation 1 has been eliminated in equation 2. This term in equation 1 results from the flow of I_{A0} current through the R_1 resistor. Referring to Fig. 3, the connection of the I_{A0} current transformer provides a shunting path which prevents I_{A0} from flowing through the R_1 resistor. The 3-unit winding is connected in the residual where $3I_{A0}$ flows and the 1-unit winding, which contains I_{A0}, is connected to shunt the R_1 resistor.

We agree that a 20,000-to-5 ratio in the tertiary of an autotransformer is impractical. It is our belief that the contribution from this winding could be neglected without any adverse effect on the relaying. However, specific data are not available to confirm this belief.

Mr. Linders' solution for clearing station III via transfer trip channels is very interesting. It would appear that the value of separate fault detectors and microwave channels for the transfer trip scheme is somewhat reduced by the application of only one signal indication for remote tripping. While a second channel is not justified economically, it is suggested that two signals be sent over the microwave channel to reduce the possibility of false tripping, particularly during testing.

The inspection for 3-phase potential appears to permit reclosing on light transformer faults which do not reduce the voltage appreciably at the remote station. This would be critical, especially if there are wide variations in normal voltage. Therefore, locking out the remote trip equipment, as outlined, should be examined carefully. The remote trip equipment may be locked out at a time when it is most valuable, i.e., when reclosing into a light transformer fault which does not lower the remote station voltage sufficiently to operate the voltage fault detectors or operate any protective relays at the remote station. Such a fault might operate the sudden pressure-type relay for tripping.

Mr. Morrison and Mr. Jansen give valuable specific applications. We will be pleased if this paper guides and aids individual thinking on each application. There was no intent to present exact solutions to these complex problems.

Operating difficulties with phase-comparison carrier relaying were mentioned. The one difficulty which the discussers did not indicate had been rectified was the unaccounted-for phase-angle differences between the local and remote signals. Mr. Morrison and Mr. Jansen did not indicate the relative magnitude of the phase shift. However, aside from normal manufacturing tolerances, some angular differences should be expected, resulting from the finite time required for both the fault and carrier signal waves to travel the length of the line. Specific field adjustments are now available in modern carrier apparatus to compensate for manufacturing tolerances and the phase shifts which vary with the line length. It is not usually expected that line length compensation will be necessary for lines less than 75 miles in length.

The blocking signal of Mr. Morrison and Mr. Jansen's case 1 should be initiated by the differential relays, since the line fault detector may not operate on all light transformer faults. Supplementing the conventional type of differential relays with a sudden-pressure relay, as mentioned in this discussion, is highly recommended for detecting light internal faults. As these pressure relays generally have a longer operating time, the blocking out of reclosing relays by their operation may not prevent reclosing where the fault is seen by the line relays.

We assume that in Mr. Hampe's third paragraph he is pointing out that in some cases single-shot reclosing is not successful because of repetitive strokes. This problem was considered beyond the scope of the present paper, but certainly seems deserving of more consideration. The problem seems to be one of distinguishing between a single permanent fault and several repetitive transient faults in rapid succession. If the differences between these two types could be identified, then a reclosing system could be designed to meet the operating requirements. In the existing schemes a minimum time interval between faults is required in order to prevent breaker pumping on permanent faults.

We choose to classify Mr. Hampe's suggestions for reclosing as follows:

1. Use the carrier blocking signal for restraining instantaneous reclosing.

2. Use dead-line or "balanced" hot-line slow-speed reclosing, or a combination of the two.

We assume that the objective of scheme 1 is to reclose as soon as the remote breaker or breakers have cleared the faults. In the conventional reclosing system, high-speed reclosing is selective, following high-speed trips, only when carrier is in service. The latter system assumes that simultaneous clearing has occurred. Mr. Hampe is attempting to obviate this assumption by confirming remote breaker clearing before initiating local reclosing.

As long as simultaneous clearing of all breakers occurs the conventional system will suffice. Therefore, Mr. Hampe's scheme is of value where sequential tripping occurs. Further, the proposed arrangement is of use only when the carrier channel is operative, since reclose restraint is dependent on the receipt of a carrier signal. It also seems reasonable to assume that where sequential tripping occurs the final breaker to clear trips by carrier. The close circuit of some of the breakers is energized at about the instant that the trip coil of the final breaker is energized.

Some or all of the difference in the times of close circuit energization can be eliminated by the auxiliary relay, which provides reclose restraint when a carrier signal is received. An additional factor is that the close circuits will be energized when the breaker mechanisms are at different positions fully closed and fully open. Thus, the actual closing times will vary and care must be taken to insure that the closing time of the first breakers to clear is long enough to allow sufficient dead time after the last breaker clears.

It appears that simultaneous closing of all breakers is not always possible with this scheme. However, the scheme appears to have merit where system stability is not a factor in the desire to reclose at the earliest possible moment.

Mr. Hampe's scheme 2, where the familiar dead-line and hot-line reclosing system is modified, seems to have merit, if hot-line reclosing on a fault arc is of great concern. His suggestion is to reclose only if the line voltage is balanced, indicating that the fault has cleared (except for three remote phase faults). This arrangement seems preferable where a line side source of 3-phase potential is available or can be economically justified.

The Induction Machine With Solid Iron Rotor

H. M. McCONNELL

E. F. SVERDRUP
ASSOCIATE MEMBER AIEE

THE MOST elementary type of rotor for the polyphase induction machine, the solid iron rotor, offers advantages in ease of manufacture and in high torque per ampere at standstill. In spite of these advantages, this type of construction has not been used extensively, even in applications most suited to its characteristics. This paper presents a rational method for the design of the induction machine with solid iron rotor. The method overcomes the usual difficulties encountered in treating the nonlinear magnetic properties of the rotor, emphasizing instead the same concepts used in the design of conventional machines. The formulas which are obtained refer directly to the physical dimensions of the machine and to the electric and magnetic loading of materials.

Electromagnetic Field Problem

Previous work on the electromagnetic field problem involved in the solid rotor machine has followed an approach based on modifying the results of a constant permeability theory. The work of Gibbs[1] and McConnell[2] is illustrative. A graphical treatment to find the power loss per unit of rotor surface area has been developed by Pohl,[3] in which the machine performance is obtained by cross reference to families of curves. The method of Pohl is an extension to nonlinear media of a method originated by Hay.[4]

Two aspects of this field problem appear. First is a consideration of the efforts made toward a solution of the eddy-current problem in solid iron under a pulsating excitation. Such a situation, typified by the solid iron cored toroid, produces an electromagnetic field without divergence by virtue of the geometry. Even in this case, purely analytical methods based on extension of the linear theory are quite awkward. Second, the solid rotor machine presents a 2-dimensional field problem, which is of higher complexity because the divergence theorem must be included as one of the field equations. This added complication further reduces the usefulness of any rigorous quasi-linear treatment.

Recent work using a limiting case theory[5] based on the idealized magnetic characteristic of Fig. 1 suggests that this same theory might be useful in obtaining a better understanding of the performance of the solid rotor machine. This theory was first suggested by Wolman[6] in 1932 as a method of attacking the problem of the rate of flux rise through a magnetic circuit subjected to a step function of excitation. In 1936, F. and G. Haberland[7] applied this theory to 1-dimensional situations involving sinusoidally pulsating excitation. The theory has been applied by Ganz[8] in the development of pulse transformer cores made from square loop magnetic materials. This paper extends the limiting case theory to the 2-dimensional problem of the solid rotor machine.

Nomenclature

f = stator frequency, cycles per second
g = effective air gap, meters
k_{p1}, k_{d1} = pitch and distribution factors for fundamental
m = number of phases
p = number of poles
s = slip, per unit
t = time, seconds
x', y, z = space co-ordinates referred to stator
x', y', z' = space co-ordinates referred to rotor
z_0' = depth of magnetic interface, meters
B_s = saturation flux density, webers per square meter
B_z = normal component of flux density
$B_{z1\max}$ = maximum value of space fundamental of air gap flux density
E = stator induced electromotive force per phase, volts rms
F = magnetic potential, ampere-turns
F_ϕ = magnetic potential of magnetizing current
F_L = magnetic potential of load current
H_X = tangential component of magnetic field intensity, amperes per meter
H_T = maximum value of tangential magnetic field intensity at rotor surface
I = stator current per phase, amperes rms
I_e = rotor eddy current per unit of periphery, amperes per meter
I_ϕ = magnetizing current per phase
I_L = load current per phase
J_y = axial current density, amperes per square meter
L = core length, meters
N = stator turns per phase in series
R_L = equivalent rotor resistance, ohms
T = electromagnetic torque, newton meters
X_m = magnetizing reactance, ohms
X_L = equivalent rotor reactance, ohms
α = phase angle, radians
β = phase angle, radians
δ = depth of penetration, meters
$\mu_0 = 4\pi \times 10^{-7}$ weber per ampere-meter
ρ = resistivity, ohm-meter
σ = conductivity, mho per meter
τ = pole pitch, meters
ω_0 = stator radian frequency, $2\pi f$

Method of Analysis

The analysis is restricted to balanced operation of the polyphase machine, and an equivalent circuit of the type shown in Fig. 2 is drawn to represent its electrical performance per phase. This equivalent circuit divides the total stator current into two parts, a magnetizing component

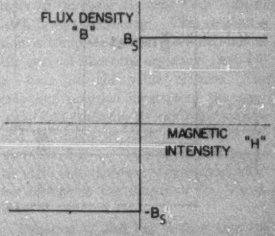

Fig. 1. Idealized magnetic characteristic

Paper 55-115, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing November 29, 1954.

H. M. McConnell and E. F. Sverdrup are with the Carnegie Institute of Technology, Pittsburgh, Pa.

This paper is an abridgement of the thesis submitted by E. F. Sverdrup to Carnegie Institute of Technology in partial fulfillment of the requirements for the degree of Doctor of Philosophy, September 1954.

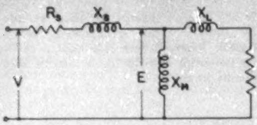

Fig. 2. Equivalent circuit, per phase star, for the solid rotor machine

and a load component. Although somewhat arbitrary, this division has a physical significance. The magnetizing current provides a magnetomotive force just sufficient to maintain the air-gap flux throughout the main magnetic circuit. The remaining component of the stator current, the load component, annuls the magnetomotive force of the rotor currents so that the required air-gap flux is not disturbed. The influence of the rotor is represented in the equivalent circuit by static circuit elements which draw a current equal to this load component.

The magnetizing impedance to be inserted in the equivalent circuit may be evaluated by standard methods. If the reluctance of the stator iron is neglected the magnetizing reactance is given by the usual design equation

$$X_M = \frac{0.9\sqrt{2}\mu_0\omega_0\tau mL(k_{p_1}k_{d_1}N)^2}{\pi g p} \qquad (1)$$

The load impedance is evaluated by the following procedure. A relation between the induced air-gap voltage E (Fig. 2) and the air-gap flux is established from Faraday's law of induction. A connection between the distribution of air-gap flux density and the magnetic potential of stator load currents is established by considering the magnetic processes in the rotor. These relationships, one between induced voltage and air-gap flux, and the other between stator load currents and air-gap flux density distribution, combine to determine both the resistive and reactive parts of the load impedance.

Air-Gap Phenomena

The voltage induced in the stator winding by the rotating air-gap flux is given by the usual equation

$$E = \sqrt{2}\frac{\tau}{\pi}(k_{p_1}k_{d_1}N)L\omega_0 B_{z1\max} \qquad (2)$$

It is assumed that harmonic voltages, which may be induced by space harmonics of the flux density distribution, are not accepted by the stator winding because of chording and distribution.

The establishment of the relationship between stator load currents and air-gap flux density distribution is a part of the rotor field analysis, to be considered in a later section. It is convenient to begin that analysis with the tangential field intensity H_x at the rotor surface as a boundary condition. This field intensity will be evaluated now in terms of the stator load current.

A rectangular co-ordinate system (Fig. 3) is fixed at the magnetic axis of the reference phase winding. The y-axis is parallel to the shaft; z is directed from the inner surface of the stator iron toward the center of the shaft; x is directed tangentially. Because of the chording and distribution of the windings, the stator currents are assumed to establish a sinusoidally distributed magnetic potential at the stator surface. Applying Ampere's circuital law to the path $ABCDA$ yields

$$\frac{\partial}{\partial x}F(x,t) = \frac{g}{\mu_0}\frac{\partial}{\partial x}B_z(x,t) - H_x\Big|_{z=g} \qquad (3)$$

in which, if the magnetic potential drop in the stator iron is neglected

$$F(x,t) = 0.9\frac{m}{p}(k_{p_1}k_{d_1}N)I\cos\left(\frac{\pi}{\tau}x + \beta - \omega_0 t\right) \qquad (4)$$

The quantity H_x at $z=g$ (equation 3) is the boundary condition to be used in the rotor field analysis. This tangential field intensity is associated entirely with currents flowing in the rotor material. The situation is somewhat analogous to the conventional induction machine in which a varying magnetic potential exists at the rotor surface because of the rotor currents, in addition to the small amount of magnetic potential required to close the main flux through the rotor iron. In the present case no magnetic field intensity is required to sustain flux in the rotor iron (Fig. 1); all the surface field intensity (H_x at $z=g$) is balanced by rotor currents.

In making the analysis it will be assumed that the field intensity at the rotor surface is a sinusoidal function with space period 2τ. Such a condition would exist truly if the air-gap flux density were sinusoidally distributed in space. However, the rotor analysis carried out on this basis shows that the resulting air-gap flux density has prominent space harmonics. The magnetic potential needed to sustain these harmonics can be obtained only from the effect of rotor currents. Therefore, the magnetic field intensity at the rotor surface cannot be truly sinusoidal. In the usual machine the air gap is so short that these higher harmonics of magnetic field intensity will

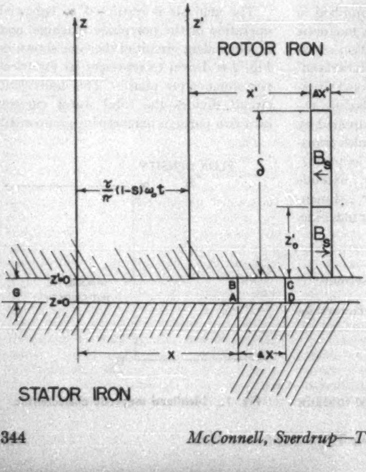

Fig. 3 (left). Stator and rotor co-ordinates, an element of rotor iron

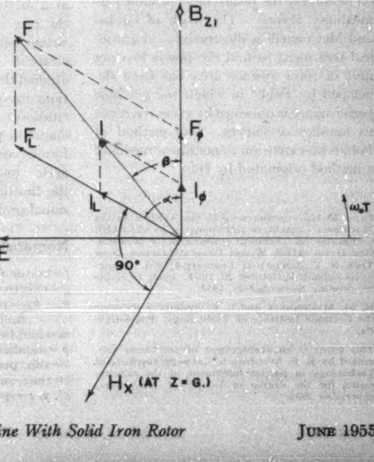

Fig. 4 (right). Phasor diagram

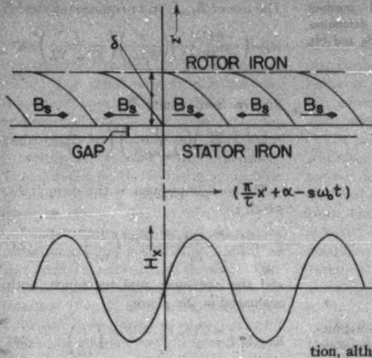

Fig. 5 (left). Traveling functions illustrating magnetic field intensity at rotor surface and magnetic state of rotor

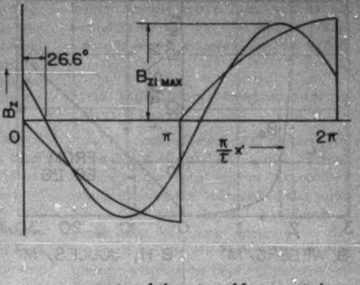

Fig. 6 (right). Air-gap flux density distribution and its space fundamental component

be neglected for the purpose of further analysis of field phenomena in the rotor. The magnetic potential required to sustain the space fundamental of the air-gap flux density will be assigned to the magnetizing current. Thus, for the fundamental components

$$\frac{\partial}{\partial x}F(x,t)=\frac{\partial}{\partial x}F_\phi(x,t)-H_x\Big|_{z=0} \tag{5}$$

in which

$$F_\phi(x,t)=0.9\frac{m}{p}(k_{p_1}k_{d_1}N)I_\phi \times \cos\left(\frac{\pi}{\tau}x-\omega_0 t\right) \tag{6}$$

$$I_\phi=\frac{E}{X_M}$$

The remaining part of $F(x, t)$ is the load component $F_L(x, t)$

$$F_L(x,t)=F(x,t)-F_\phi(x,t)$$

$$F_L(x,t)=0.9\frac{m}{p}(k_{p_1}k_{d_1}N)I_L \times \cos\left(\frac{\pi}{\tau}x+\alpha-\omega_0 t\right) \tag{7}$$

$$\frac{\partial}{\partial x}F_L(x,t)=-H_x\Big|_{z=0}$$

The quantities E, I_ϕ, I, I_L, F_ϕ, F, F_L α, β are shown on the phasor diagram of Fig. 4. The unknown angles α and β are determined from the rotor field analysis to follow.

Rotor Field Analysis

Rotor co-ordinates are denoted by primed symbols x', y', z' with the origins shown in Fig. 3. The traveling functions $f(\pi x/\tau-\omega_0 t)$ referred to stator co-ordinates take the form $f(\pi x/\tau'-s\omega_0 t)$ referred to rotor co-ordinates. The origins $x=0$ and $x'=0$ coincide once per revolution, although this has no bearing on the analysis.

A 2-dimensional field is assumed, implying that end effects are neglected. The use of a rectangular co-ordinate system implies that the rotor curvature is not important. As pointed out by Concordia[9] this procedure is justified even for 2-pole machines if the ratio δ/τ is small. These two major assumptions will be discussed in detail later.

The rotor surface is laid off in strips of width $\Delta x'$, one of which is shown in Fig. 3. Each surface element thus defined experiences a tangential magnetic field intensity pulsating at slip frequency and of amplitude H_T, where

$$H_T=0.9\frac{\pi}{\tau}\frac{m}{p}(k_{p_1}k_{d_1}N)I_L \tag{8}$$

as a consequence of equations 7. Because of the traveling excitation, neighboring elements see the same amplitude of pulsating field intensity but with a time phase displacement. The limiting nonlinear field theory of reference 6 will be applied to each rotor element individually.

The flux density at any point within the rotor may be changed only if the field intensity is zero (Fig. 1). As is shown in reference 5, this statement requires that the magnetization of the rotor elements proceed by the propagation of an interface between regions magnetized tangentially in opposite directions. At this interface the magnetomotive force of the eddy currents within the element must be balanced by the magnetomotive force externally applied to the element. Quantitative application of these arguments establishes the location of the interface within the element as a function of time. Consideration of all such elements leads to the distribution of eddy currents within the rotor. The relationship between the load component of the stator current and the rotor eddy currents is established in this way.

It is shown in reference 5 that a uniform current density exists between the element surface and the moving interface, while no eddy current flows on the other side of the interface. The density of eddy currents is

$$J_Y=-2B_s\sigma\frac{d}{dt}z_0' \tag{9}$$

when the flux density is being changed from $-B_s$ to $+B_s$. Since this density is uniform, the total eddy current contained in the element is found from

$$I_e=-2B_s\sigma z_0'\frac{d}{dt}z_0' \tag{10}$$

The field intensity at the rotor surface must balance I_e of equation 10 so that the field intensity at $z=z_0'$ is zero. Therefore

$$H_T\sin\left(\frac{\pi}{\tau}x'+\alpha-s\omega_0 t\right)=2B_s\sigma z_0'\frac{d}{dt}z_0' \tag{11}$$

Integration of equation 11 yields the depth of the interface

$$z_0'=\sqrt{\frac{2H_T}{s\omega_0\sigma B_s}}\cos\frac{1}{2}\left(\frac{\pi}{\tau}x'+\alpha-s\omega_0 t\right) \tag{12}$$

Equation 12 expresses a traveling wave function which describes the position of the interface at any value of (x', t) within the interval $0<(\pi x'/\tau+\alpha-s\omega_0 t)<\pi$. At the extreme of the interval where the argument $(\pi x'/\tau+\alpha-s\omega_0 t)$ has the value π, the process of reorienting the active layer of the rotor material from $-B_s$ to $+B_s$ is just beginning. This reorientation is complete at the other extreme of the interval where the argument $(\pi x'/\tau+\alpha-s\omega_0 t)$ has the value of zero. The traveling function illustrating the magnetic field intensity at the rotor surface and the magnetic state of the rotor are shown in Fig. 5. This pattern moves to the right with the wave of excitation, without change in the shapes of the boundaries.

Equation 12 and Fig. 5 show that the total tangential flux carried by each rotor

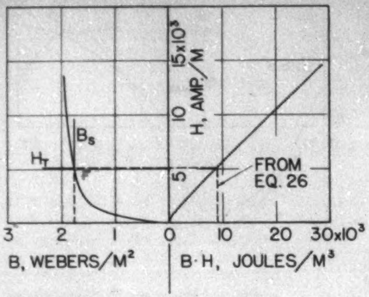

Fig. 7 (left). BH product construction to determine operating values of B$_S$ and H$_T$

element per unit of axial length varies according to the position of the element. This state of magnetization can be supported only if flux enters and leaves the rotor surface. It will be recognized most emphatically at this point that the rotor field analysis has made use of the answer to a 1-dimensional field problem to describe a 2-dimensional field. Considerable liberty has been taken with the field theory in so doing; strict conformance to field theory would demand that the divergence theorem be put into the problem initially. Instead, this theorem is used now to determine the space wave form of air-gap flux density. Essentially, this step recognizes that magnetic flux must be continuous but it treats the two rectangular components separately.

Consideration of Fig. 5 shows that

$$B_z(x',t)=2B_s\frac{\partial}{\partial x'}z_0' \qquad (13)$$

over half-cycle intervals. Thus

$$B_z(x',t)=-\frac{\pi}{\tau}B_s\sqrt{\frac{2H_T}{s\omega_0\sigma B_s}}\times \sin\frac{1}{2}\left(\frac{\pi}{\tau}x'+\alpha-s\omega_0t\right) \qquad (14)$$

Only the space fundamental of air-gap flux density is of interest because of the filtering action of the stator windings. By Fourier analysis, this fundamental component is

$$B_{z_1}=-\left(\frac{4\sqrt{5}}{3}\right)B_s\times \frac{\delta}{\tau}\sin\left(\frac{\pi}{\tau}x'+\alpha-s\omega_0t-\tan^{-1}0.5\right) \qquad (15)$$

where the maximum penetration of the field into the rotor is

$$\delta=\sqrt{\frac{2H_T}{s\omega_0\sigma B_s}} \qquad (16)$$

The air-gap flux density and its space fundamental are shown in Fig. 6.

It is noted in equation 15 that δ is fixed by $B_{z1\max}$ and the machine constants. Since in turn the fundamental of air-gap flux density is fixed by the induced voltage, it follows that δ varies but slightly over the normal operating range of the machine. Whether the handling of the divergence theorem as used in this analysis is reasonable depends upon the ratio of δ/τ, which by equation 15 is

$$\frac{\delta}{\tau}=\frac{3}{4\sqrt{5}}\frac{B_{z1\max}}{B_s} \qquad (17)$$

or about 0.1 for the usual design. Thus the use of the 1-dimensional field problem seems justified. The arguments summarized in the previous few equations also justify the use of single-phase excitation by Pohl[3] to determine the characteristics of the rotor material.

Load Resistance and Reactance; Developed Torque

Information is now available to complete the equivalent circuit. The first calculation is to determine α, since it fixes the rotor power factor (Fig. 4). Since B_{z1} must be a cosine function of time when viewed at $x=0$, it follows from equation 15 that

$$\alpha=-63.4 \text{ degrees} \qquad (18)$$

must be substituted into equations 7. Thus the load component of stator current always lags the induced voltage by 26.6 degrees. The rotor power factor is always 0.895, independent of the slip or the voltage. This result is confirmed by Gibbs.[1]

The magnitude of I_L is now computed. From equation 16

$$H_T=\frac{1}{2}s\omega_0\sigma B_s\delta^2 \qquad (19)$$

The use of δ from equation 17 yields

$$H_T=\left(\frac{9}{2\times16\times5}\right)\left(\frac{s\omega_0\sigma\tau^2}{B_s}\right)B_{z1\max}{}^2 \qquad (20)$$

The use of $B_{z1\max}$ from equation 2 yields

$$H_T=\left(\frac{9\pi^2}{4\times16\times5}\right)\left(\frac{\sigma}{B_s\omega_0}\right)\left(\frac{1}{k_{p_1}k_{d_1}NL}\right)^2 sE^2 \qquad (21)$$

Finally, from equation 8

$$I_L=\frac{1}{64}\left(\frac{p\tau}{mL^2}\right)\left(\frac{1}{k_{p_1}k_{d_1}N}\right)^2\left(\frac{1}{B_s\rho f}\right)sE^2 \qquad (22)$$

The load impedance is the ratio E/I_L, which is

$$Z_L=\frac{64mL^2(k_{p_1}k_{d_1}N)^2B_s\rho f}{p\tau}\left(\frac{1}{sE}\right) \qquad (23)$$

and the resistance and reactance, both evaluated at slip s, are

$$R_L=57.2\frac{mL^2(k_{p_1}k_{d_1}N)^2B_s\rho f}{p\tau}\left(\frac{1}{sE}\right) \qquad (24)$$

$$X_L=28.6\frac{mL^2(k_{p_1}k_{d_1}N)^2B_s\rho f}{p\tau}\left(\frac{1}{sE}\right)$$

as determined by the constant phase angle ($\tan^{-1}0.5$).

The air-gap power is the torque multiplied by the synchronous speed. Carrying out this computation for the torque yields

$$T=\left[\frac{p^3\tau}{900L^2(k_{p_1}k_{d_1}N)^2B_s\rho f^2}\right]sE^2 \qquad (25)$$

The equivalent circuit constants (equation 25) and the developed torque (equation 4) contain the saturation induction B_s as a parameter. Since the magnetic materials used in rotor construction are not exactly represented by the characteristic of Fig. 1, the value of B_s to be used is open to question. An assumption originated by Rosenberg, and discussed in detail in reference 5, proposes that the value of B_s to be used is that taken from the normal magnetization curve corresponding to the maximum field intensity. This assumption forms the basis of the method now proposed to determine the operating values of B_s and H_T.

Equation 21 may be rewritten in the form

$$H_TB_s=\left(\frac{9\pi^2}{4\times16\times5}\right)\left(\frac{\sigma}{\omega_0}\right)\left(\frac{1}{k_{p_1}k_{d_1}NL}\right)^2 sE^2 \qquad (26)$$

in which the product (H_TB_s) describes the magnetic loading of the rotor material. Thus, for a given slip and induced voltage, the value of this product is determined. It is necessary only to plot the function H_TB_s versus H_T as obtained from the normal magnetization curve. The operating value of (H_TB_s) is taken from equation 26. The construction to find H_T and B_s is illustrated in Fig. 7.

End Effects

The analysis has neglected any extra impedance introduced at the ends of the rotor. The usual procedure in conventional machines is to group the resistance and reactance of the end connections together with the squirrel-cage impedance to obtain an over-all rotor impedance. The situation in the solid rotor machine is quite different because of the nonlinearity.

Rotor currents entering the end regions cause an electric potential to appear at the ends of each rotor element. The electric field established by the moving interface (Fig. 3) must balance both the potential drop (due to eddy currents) within the element and the added potential at the ends. Thus the interface must move faster than indicated in equation 9. Consequently, a given value of H_T yields a greater depth of penetration than given by equation 16. But the depth of penetration is actually fixed by the maximum air-gap flux density, as shown in equation 17; therefore the presence of the end ring potential reduces the operating value of H_T and consequently reduces the load component of stator current. It is as though an impedance were placed in series with the rotor impedance of equations 24. The evaluation of this added impedance will be discussed qualitatively in the following paragraphs.

Throughout the analysis it has been assumed that the boundary condition at the rotor surface is a sinusoidally distributed traveling wave of tangential magnetic field intensity. The rotor current which flows in response to this surface excitation has a nonsinusoidal distribution in both density and depth. However, the total current carried by the active part of the rotor is sinusoidally distributed.

The presence of the end ring potential will alter the space distribution of rotor current density, causing it to depart from the ideal shown in Fig. 5. Still, the total rotor current will be sinusoidally distributed to satisfy both the boundary condition and the limiting nonlinear theory of eddy currents. This argument is independent of the type of end ring used.

The presence of the end ring causes a reduction in the operating value of H_T as shown previously. In addition, a change in the density of rotor currents is brought about. Therefore, the end ring both adds an impedance to the circuit and causes a change in the impedance offered by the active layer itself. This type of interaction is typical of nonlinear systems.

COPPER END RING

In the case of copper end rings, the end ring potential is sinusoidally distributed, as the end ring is made of a linear material. Since the resistivity of copper is considerably smaller than that of steel, the end ring potential will be small if the end ring and the active layer are operated at about equal current densities. Under such conditions the distortion of current density in the active layer will be of second order, so that the end ring and active layer impedances may be added directly.

STEEL END REGION: CONTINUATION OF ACTIVE LAYER

In the case of steel end regions, the sinusoidally distributed active current entering the end region encounters nonlinear magnetic material of the same kind as the active layer. The depth of penetration of these currents is determined by the current and rotor frequency, whereas the depth of penetration in the active layer is determined by the required air-gap flux (equation 17). The process in the end region is similar to conductive heating with a forced current, establishing a potential at the end ring which depends on this current, its depth of penetration, and its frequency. The phenomena in this active layer and the end regions are related in a nonlinear manner, the variables being the ratio of pole pitch to core length, the rotor frequency, and the total air-gap flux. Theoretical work on this problem is in process.

Experimental Work

The performance of the solid rotor machine was investigated experimentally using a commercial 2-phase stator. A rotor was constructed using *SAE 1020* steel with a 3/16-inch overhang on each end, which formed the end path for rotor

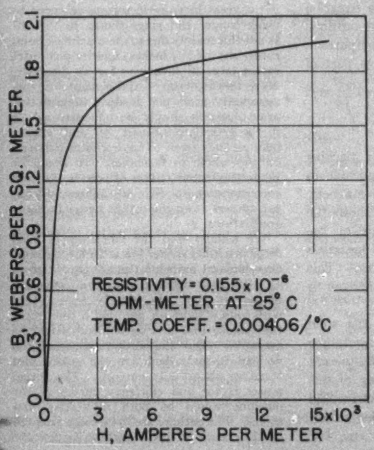

Fig. 8 (left). Electric and magnetic properties of rotor material

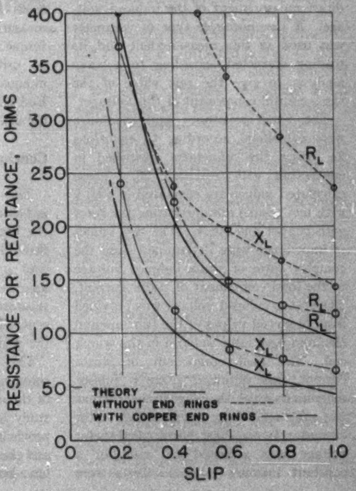

Fig. 9 (right). Calculated values and test results for rotor equivalent circuit parameters

currents. After the test program on this rotor was completed, the overhang was removed and a soft copper end ring 1/4 by $1^1/_4$ inch in cross section was soldered to each end. The pertinent machine data are as follows:

General

Rated power output, 3/4 horsepower.
Rated voltage, 440 volts.
Rated frequency, 60 cycles per second.
Number of phases, 2.
Number of poles, 4.

Stator Winding Data

Number of turns per phase connected in series, 1,080.
Winding pitch factor (fundamental), 0.940.
Winding distribution factor (fundamental), 0.903.
Winding resistance per phase at 25 degrees centigrade, 27.2 ohms.

Machine Dimensions

Stator core length, 0.0635 meters.
Pole pitch, 0.0870 meters.
Physical air gap length, 4.07×10^{-4} meters.
Stator Carter coefficient, 1.155.
Effective air-gap length, 4.70×10^{-4} meters.
Stator bore diameter, 4.375 inches.
Rotor diameter, 4.343 inches.
Ratio-active rotor length to pole pitch, 0.73.

Electric and magnetic properties of the rotor material are given in Fig. 8. This information was obtained from tests made upon a solid ring cut from the same piece used for the rotor.

The stator was equipped with a 5-turn full-pitch search coil made of no. 30 copper wire and cemented to the surface of the stator. This search coil was used to examine the wave shape of the radial air-gap flux density distribution and for a direct measurement of the induced voltage. A thermocouple type of voltmeter was used in this measurement and its reading corrected according to a wave analysis to give the rms value of the fundamental component of this voltage.

The rotor resistance and reactance were calculated according to equations 24, using the refinement described in connection with equation 26. These calculated values are compared in Fig. 9 with test results obtained using the rotor with copper end rings. The test values of impedance were determined from the complex ratio of stator-induced voltage to the load component of stator current. The stator-induced voltage was obtained from observed values of the fundamental electromotive force induced in the search coil. The load component of stator current was obtained from a phasor diagram in which the magnetizing current was subtracted from the measured stator current. In each test, the applied stator voltage was adjusted to maintain a constant induced voltage. Tests were made for two other induced voltages, 190 and 366 volts rms, with similar agreement between calculated and test values.

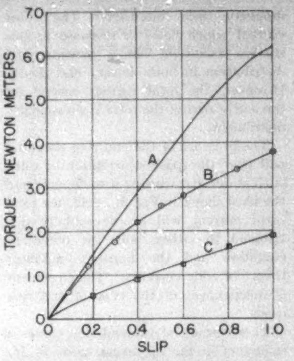

Fig. 10. Calculated values and test results for torque characteristic

Curve A, theoretical
Curve B, rotor with copper end rings
Curve C, rotor with steel end rings

Tests on the rotor without copper end rings show a considerable increase in rotor impedance. This result is consistent with the qualitative discussion of end effects. These test values are also shown in Fig. 9 for a 263-volt induced voltage.

During the tests for verification of the equivalent circuit, the torque was measured by dynamometer. These torque measurements are shown in Fig. 10. The torque calculated according to equation 25, using again the refinement outlined in equation 26, as shown for comparison. End effects account for a large part of the discrepancy noted.

Conclusions

This study of the solid rotor machine is based on a field theory applicable to the limiting case of saturable magnetic materials. As such, the study shows the way in which the dimensions of the machine and the properties of materials separately affect the performance. This separation of attributes is significant to the design process.

This and other studies of the solid rotor machine indicate the importance of the end effect. However, the present study leads to an understanding of this problem in terms of the electric field and the rotor current distribution, which have been obscure.

The general results are in agreement with those published by earlier investigators, who use with great ingenuity adaptations of the classical eddy-current theory.

Discussion

W. J. Gibbs (The British Thompson-Houston Company, Ltd., Rugby, Warwickshire, England): The most striking result of the authors' calculations and tests is the great increase in torque achieved by using copper end rings shown in Fig. 10. Is not this mainly due to the machine's being rather short ($2^1/_2$ inches) and its pole pitch rather large ($3^1/_2$ inches) for its diameter? Nevertheless, the improvement is unexpectedly good and it does suggest that some research should be concentrated on a theoretical treatment of end effects, because they seem to have a vital influence on the whole performance. It would be interesting to see curves of primary current corresponding to Fig. 10, because torque per ampere is an important figure in many applications.

We usually find the efficiency of solid rotor machines rather low. In the authors' experimental machine the air gap is given as 0.018 inch which is a normal induction motor air gap. We should expect that with such a short air gap and a solid rotor the surface iron loss on no load would be excessive. Did the authors measure the no-load losses? And are the stator slot openings abnormally narrow? The actual power factor and efficiency curves of the machine would be both interesting and useful. The authors are to be congratulated on their work in this important field.

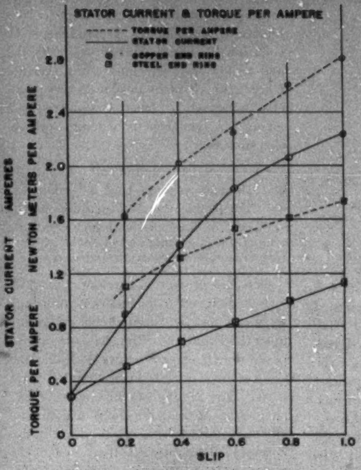

Fig. 11. Torque per ampere corresponding to Fig. 10

H. M. McConnell and E. F. Sverdrup: We are grateful to Mr. Gibbs for his contribution to the paper. His comments on end affects agree with our conclusions. A relatively short machine was used in the experimental work, although we believe that the machine chosen is fairly representative of commercial practice.

A curve showing the torque per ampere corresponding to Fig. 10 is shown in Fig. 11. Reference to manufacturers' data for this motor with its normal squirrel-cage rotor shows that the locked torque per ampere with the solid rotor, with copper and rings, is about three times the value with the squirrel cage.

The efficiency of the solid rotor machine is low if it is compared with a squirrel-cage machine of equal dimensions, considering in each case the slip required to develop name plate torque. This low efficiency is a property of any machine with high-resistance rotor. This point is emphasized to put the rotor surface loss in proper perspective. The rotor surface loss is naturally large in the solid rotor machine, but it is not predominant in causing low efficiency.

An approach to the surface loss problem can be made by classical eddy-current theory, using the residual permeability of the rotor iron and using as boundary conditions the known harmonic content of the stator magnetic potential.

Unfortunately, data are not available to show the no-load loss, the power factor, or efficiency. However, examination of Fig. 10 shows that the rotor impedance does indeed yield a current locus which is a straight line (equation 24); the theory also predicts that the power factor with respect to induced voltage approaches asymptotically the value 89.5 per cent. The tests confirm this value. The experimental machine was made up using a stator of standard manufacture, and the stator slot openings were normal.

Improved Fast-Acting Thermal Relay and Its Application as a Cage Winding Protective Relay for Synchronous Machines

JOHN BAUDE
ASSOCIATE MEMBER AIEE

THERMAL relays have been used in the past for a great variety of purposes because they are simple and reliable devices, but they are relatively slow in action. A description of design and application of a new fast-acting thermal relay for synchronous machine protection and control purposes follows. The usual application of thermal relays makes use of only the heating part of a total thermal cycle for purposes of motor control and protection. Such practice involves the simple direct or indirect heating of a bimetallic strip, which acts upon a contact-making device which in turn is arranged to stop motor operation, give an alarm, or perform any other desired function.

The thermal problem involving the relay can be studied with the help of the following equation.[1]

$$T_1=\frac{W}{h}\left(1-\frac{1}{\epsilon^{\frac{th}{MS}}}\right) \qquad (1)$$

where

M = mass of bimetallic element
S = heat capacity per gram, joules per gram per 1 degree centigrade
W = rate at which heat is applied to mass M, watts
h = rate at which heat is exchanged between the medium and the mass M per degree difference in temperature, watts per 1 degree centigrade
T_1 = temperature increase of bimetallic strip sufficient to cause deflection for contact operation
t = time in seconds to cause a temperature increase of T_1
ϵ = 2.718

The art of delaying the heating of the thermal relay's bimetallic strip during the first part of the thermal cycle has advanced to the point where appreciable close matching of machine thermal characteristics with the rate of heating of the thermal relay is obtained.

Referring to equation 1, it is obvious that thermal relays are ideal for a relatively long time out period, and it is also apparent that for a constant value of T_1 an exponential relation exists between W and t which is illustrated in Fig. 1. This means that, for relatively small values of t, the energy transfer requirement still varies in line with the existing exponential relation between W and t, and large amounts of energy are required for a short operation time regardless of whether the bimetallic strip is used as a heating current conductor or the operating element is heated indirectly. In normal motor protection practice it is not required that the thermal relay, simulating machine thermal characteristics, act very fast. If, however, the thermal relay operation can be increased to approximately 4 seconds with a reasonable operating current, say 2 to 3 amperes at 125 volts d-c such a de-

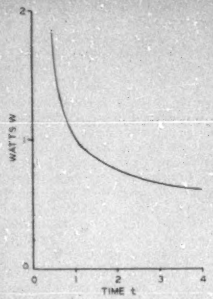

Fig. 1 (left). Energy requirement of thermal relay

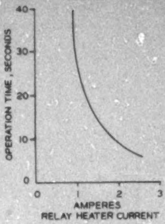
Fig. 2 (right). Heating characteristic of thermal relay



vice could help solve a difficult synchronous machine problem and provide inexpensive protection for the most vulnerable part of a synchronous motor or synchronous condenser, which is its cage or amortisseur winding. This winding is used for starting purposes and has a very limited thermal capacity which usually varies between 4 to 10 seconds at locked rotor condition. This starting winding has no outside connections. The rate of heating of this winding is substantially proportional to the slip cycles per second of the motor. In reduced voltage starting, it is also inversely proportional to the ratio of the square of the line voltage to the square of the reduced voltage during starting conditions.

The ideal cage winding protection relay should operate on a slip cycle per second basis and in accordance with the terminal voltage of the machine. At locked rotor condition the temperature rise in the cage winding of a specific motor may be well over 100 degrees centigrade per second. A fast-acting thermal relay can be arranged to simulate the thermal characteristic of the cage winding of a motor by connecting it to the control voltage source, and inserting various resistors into its circuit, which are controlled in accordance with the conditions under which the motor has to operate. The most important requirement for such a relay is reliable operation. Operating speeds up to 4 seconds with moderate power requirements are also recommended.

Fig. 2 shows the heating characteristics of a special fast thermal relay at normal ambient temperature. This relative high speed was obtained by modification of a standard relay in such a manner that the heating element was sandwiched between two bimetallic strips as shown in Fig. 3 in order to provide the necessary concentration of energy transfer from the source to the bimetallic strips.

The application of a thermal relay of this type can be expanded to include simulation of the machine's cooling characteristic if a residual current is circulated through the heater of the thermal relay after the heating period is completed. In Fig. 4 the cooling characteristic of the same relay is shown under normal ambient temperatures; in the construction of such a relay experience has shown that the shorter the heating period is compared with the cooling the more difficult it is to find a satisfactory design solution. If equation 2 for cooling is compared with equation 1 for heating, the existing design limitations can be seen more readily.

The cooling period of the total thermal cycle can be studied with the help of equation

$$T_D = \frac{1}{\epsilon^{\frac{ht}{MS}}} T_1 \qquad (2)$$

where

T_D = temperature difference between the bimetallic element and the medium at any time t

T_1 = the initial temperature before cooling

T_D will now be considered as the necessary temperature difference at which the relay will reset after heating to a time out point; it is noticed from equation 2 that the reset time t varies directly proportional with the mass M which is a design factor of the relay. The greater the mass the longer the natural reset time has to be, keeping other factors constant. A residual current during cooling will act to restore lost energy and lengthen the reset time by raising the ultimate temperature of the bimetallic element in accordance with equation 1. The typical curves of Figs. 2 and 4 show the performance of a thermal relay with all of its design factors properly balanced to meet special requirements for synchronous machine protection such as:

1. Low energy requirements.
2. Minimum trip-out time 4 seconds.
3. Controllable reset time up to 15 minutes.
4. Long life combined with high operating temperature making additional ambient temperature compensation unnecessary.

The cage protection thermal relay, Fig. 3, was designed to include an additional separately heated thermal element acting upon the same contact mechanism for purposes of an over-all check of relays during the starting period on a common time basis. The timing of this separate element is based upon normal functioning of all relays and starting of the motor under normal load conditions. If any one of the relays fails to function properly, this separate part of the cage protection relay will function to act as an incomplete sequence relay and take the motor off the line.

Application of Cage Protection Relay

The application of the combined cage protection and incomplete sequence relay is described in the following. Fig. 5 is a schematic diagram for full-voltage starting and Fig. 6 for reactor starting.

FULL-VOLTAGE STARTING SCHEME, FIG. 5

The closing circuit of circuit breaker *42* is energized by a push button, a control switch, or any automatic device having a momentarily operated normally

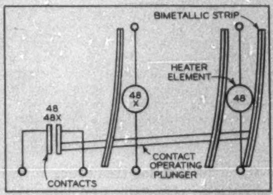


Fig. 3. Thermal relay

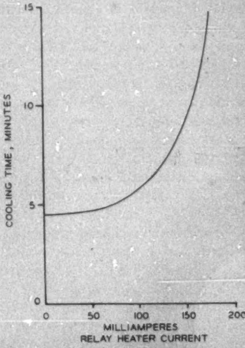

Fig. 4. Cooling characteristic of thermal relay

open or a maintained contact. The undervoltage and reverse phase relay *47* has one of its contacts connected in series in the closing circuit in order to prevent starting of the motor on low voltage. Provided that contact *47* in the closing circuit is closed, assuring proper voltage, the operation of the starting push button will pick up *42X* and energize the closing coil of circuit breaker *42CC;* upon completion of the closing cycle of the circuit breaker, relay *42Y* by action of its contacts will either lock itself in if the starting push button is of the maintained contact type or will drop out when the push button is released. This type of control is standard and is antipumping. During the starting cycle and before synchronization, the synchronous motor is protected by primary relays, including generally single-phase induction overcurrent relays with instantaneous tripping attachments, and thermal overload relays. When required, differential relays, current balance relays, and other primary protective relay may be added easily to this standard control scheme.

Cage (Starting) Winding Protection

Cage winding protection of the synchronous motor is provided by means of thermal relay *48*, which is connected at the beginning of the starting cycle into the control circuit by action of a normally open contact of auxiliary relay *13X*. The action of thermal relay *48* is controlled by two resistors *R4* and *R5*. *R4* is adjusted to provide sufficient time for starting under normal conditions. Resistor *R5* is short-circuited by the contact of a field current failure relay *40* and a normally closed contact of field contactor *41*. As soon as the starting cycle is completed and the field contactor closes, *R5* is cut into the circuit and current continues to flow through the heater element of thermal relay *48*. This current is reduced to a value which may be adjusted to delay the cooling of the thermal relay to the point where it approximates the rate of heat dissipation of the cage winding of the motor under normal running conditions. In this way maximum co-ordination of the cage protective relay with the thermal characteristics of the cage winding of the motor is accomplished. This method of co-ordinating the operation of relay *48* with the characteristics of the cage winding of the motor is carried further for cases in which the synchronous motor has been overloaded to the point of pullout or shutdown. To prevent an excessive number of unsuccessful restarts under adverse operating conditions the residual heater current of the thermal relay is increased by circulating current from the source through relay contact *48* through a normally closed contact of relay *13X* to a tap on resistor *R5* through the heater element of thermal relay *48* through resistor *R4* and back to the source. The increased residual current through the relay will delay cooling of the thermal relay further and will simulate the cage winding's rate of cooling under conditions of lockout due to overload.

Refinements

Other extra features that may be added to this cage winding protection scheme include locked rotor protection by attaching a zero speed switch to the motor, the contact of which is closed when the motor is at standstill. This contact short-circuits a portion of one of the series resistors in the relay circuit of thermal relay *48* and cuts down the operating time of this relay to a point where it matches the allowable time which the motor can operate with full voltage on its terminals but with the rotor locked. If it is impossible to equip the motor with a zero speed switch, the same thing can be accomplished by operating an underfrequency relay from taps on the discharge resistor of the motor field circuit. The contact of this underfrequency relay is connected into the circuit in the same manner as a contact of the zero speed switch just described.

* Zero speed switch on motor is required if locked rotor protection is desired

Field Application

Field breaker *41* is controlled by field application relay *13*. This relay is a simple clapper-type relay which carries two coils. One of these coils, *13A*, acts as a polarizing coil and is connected into the field supply circuit by means of a normally open contact of relay *13X*. The other coil, *13B* of field application relay *13*, is connected in series with the motor field, the discharge resistor, and a normally closed contact of field contactor *41*. During the starting cycle coil *13B* therefore will be under the influence of the induced field current during the starting cycle and before the field contactor closes. The combined action of coils *13A* and *13B* provides that the two superimposed fluxes cancel each other at a certain point of each positive half-cycle, which causes relay dropout based upon time constant and air-gap adjustments. Relay *13* is adjusted to drop out at approximately 95 to 98 per cent of synchronous speed. Once the field contactor has closed under the influence of the field application relays *13*, the flux from coil *13A* is increased by cutting out a portion of its series resistance to prevent subsequent pickup on field current surges.

The control circuit of the field contactor functions as follows: At the instant the circuit breaker of the motor is closed, field application relay *13* will pick up and its normally closed contact *13*, which short-circuits the auxiliary relay *13X*, opens up. When *13X* is energized it locks itself in through a resistor and a normally open contact of the circuit breaker. This relay is necessary to set up the circuit for the closing coil of the field contactor which otherwise might pick up simultaneously with field application relay *13*. After the circuit for closing of the field contactor has been set up by field application auxiliary relay *13X*, the field contactor will close when relay *13* drops out and closes its contact *13*. A circuit in this form is set up to provide for automatic resynchronization on pullout. Under certain circumstances and with certain types of load it may be necessary to shut down as soon as the synchronous motor has pulled out of step. Shutdown is provided by the addition of a relay *41X*, the contact of which is connected in series with a normally closed contact of the field contactor. This arrangement will energize trip coil *42TC* of the circuit breaker and trip this breaker instantaneously on pullout. Tripping of the circuit breaker is accomplished either by push button or by any other automatic control device.

To check the over-all performance of all the relays during the starting period, a so-called incomplete sequence relay *48X* is provided. This relay is actually part of the cage winding relay as previously explained but consists of a separate heater element operating on the same contact assembly of relay *48*. This heater is adjusted to provide backup protection for all of the other automatic devices and the time setting is slightly longer than it normally takes to synchronize the motor.

To provide the operator with some means which will indicate when relay *48* has automatically reset after a lockout operation, a reset indicating lamp is provided in series with contact *48-48X* to indicate when this relay has reset. This arrangement cuts down lost operating time because of a lockout.

REACTOR STARTING, FIG. 6

The principle of operation of the reactance starter is the same as described in the foregoing for the full-voltage starter. The

main difference in operation is the fact that the starting cycle involves the closing of two circuit breakers instead of one. The operation of field application relay *13* is exactly the same as described for the full-voltage starter. The cage winding protection relay *48* is further modified in its operating characteristics by a normally open contact of the running breaker *42* which provides for the insertion of different series resistance values to co-ordinate the operation of relay *48* with the variation in the heating time of the cage winding under full-voltage conditions as against reduced-voltage operation. A timing relay device *19* is provided as a transfer and lockout relay. The purpose of this relay is to energize the running breaker closing circuit *42* after a predetermined time. This function is performed by contact *19T1* of this relay. Another contact *19T2* in series with a normally closed contact of the running breaker *42* is connected into the trip circuit of the starting breaker *6* to protect the starting reactor and open up the starting breaker in case the running breaker should not close for any reason.

The connection marked Δ can be made to provide for immediate shutdown on pullout. Relay *48X* again acts as an incomplete sequence relay and its operation somewhat parallels the function of transfer relay *19*.

The autotransformer starting scheme involves the proper co-ordination of three breakers. Starting breaker *6B*, neutral breaker *6A*, and running breaker *42* are interlocked in such a way that the neutral breaker *6A* is closed first, then the starting breaker *6B*, and after a period of time the running breaker *42* is closed and breakers *6B* and *6A* are open. The principle of operation otherwise is exactly the same as described for the reactance starter.

Conclusion

The previous description of a special thermal cage protection and incomplete sequence relay for synchronous machines outlines the practical design limits which were reached for a simple thermal relay for this type of application. Adequate protection of a synchronous machine's cage winding is one of the most important requirements for modern motor applications because it eliminates the danger of ruining the motor as the result of the operator's misjudgment of the motor's thermal capacity. Also adequate protection for the starting reactor is provided when reduced-voltage starting is used. A simple indicating lamp which indicates the position of the cage protection and incomplete sequence relay will help the operator to see exactly when the motor is ready to go through another complete starting cycle, and will be especially appreciated in industries which impose frequent overloads upon their motors.

Since the copper in the cage winding is active only during starting, the tendency exists among motor designers to decrease the amount of copper which is put into the starting winding of motors because all inactive material is eliminated as much as possible. The knowledge that efficient cage protection is always provided may be considered an important factor in altering present design practice. Furthermore, there seems to exist a discrepancy at present between the standards covering thermal capacities of starting reactors and the thermal capacity which is commonly designed into the cage winding of a motor. It seems that adequate cage protection automatically provides starting reactor protection on a precise basis which would permit revision of the present standards.

Discussion

H. C. Barnes (American Gas and Electric Service Corporation, New York, N. Y.): The author's coverage of the problem of motor cage windings points out the need for an improvement in motor standards. It is extremely difficult for the relay designers and engineers to protect motors adequately when such great variations exist.

On several occasions, we have endeavored to correlate thermal relay tripping times with motor thermal characteristics. The relay manufacturer is extremely evasive on the question of margin between relay time and motor thermal capability, particularly in the case of the heaters normally supplied with magnetic contactors. He will tell you that the curves are based on an "average" of motor characteristics but will not produce the curves from which the "average" is taken. His stock answer is that curves for each motor should be obtained from the motor manufacturer. The motor manufacturer will give some equally evasive answer to the effect that each motor has its own characteristics which can be determined only by tests which are economically prohibitive. With such answers determination of adequacy of protection is difficult, to say the least.

In addition to this lack of information, there are the other problems of ambient temperature, particularly if the thermal relay and motor are in widely separated areas, the difference in cooling characteristics between the relay and motor, and the difficulty in testing thermal relays because of the long wait for them to cool to ambient, all of which discourage any feeling of confidence in thermal protection of motors.

When it is realized that thermal overload protection generally consists of an effort to make the minute mass of the thermal element act just like the comparatively huge mass of the motor, it becomes evident that correlation will be difficult. Therefore, perhaps the author's approach of basically establishing a definite time and then varying it for the starting cycle or for locked rotor is more realistic than trying to match all points of the thermal curve.

Perhaps this could be carried further to eliminate the thermal relay and its inherent weaknesses and utilize synchronous timers instead. The induction overcurrent relay is a modification of this in that in general it trips in a fairly definite time once a certain percentage overload is reached. It makes no effort to match motor thermal characteristics. This type of protection has been fairly satisfactory although admittedly motor damage could result from continuous operation in the band between motor rating and pickup of the relay. A properly functioning thermal relay would, of course, permit some operating advantage where short-time overloading above the induction relay pickup setting was considered desirable. Both the definite timer, and the thermal device as applied here, would have the advantage of being applicable where no current transformers were available.

There does not appear to be a statement as to the operating tolerance of this device Such information would be of interest.

Fig. 3 appears to be intended to illustrate the advantage of placement of a bimetal on each side of the heater to take full advantage of heat availability. It is not clear just what this advantage is. It would seem that each would react to one-half the heat and each would travel the same amount. Are these additively coupled in some way?

The use of the polarized field application relay with one winding across the discharge resistor is one way of indicating the approach of synchronous speed. We have always used the simple plunger overcurrent relay in the secondary of one of the armature circuit current transformers of large synchronous condensers for this purpose. This seems to have the advantage of reduced exposure of field circuits to grounds or short circuits.

Inclusion of the incomplete start function *48* as a part of this device might be of disadvantage because of the need to await cooling if the full time is to be realized. A synchronous timer might be better.

This seems a good time to point out that the AIEE Relay Committee has established a Project Committee on Motor Protection. The purpose is to review present practices and to prepare an application guide for motors and synchronous condensers. The material presented in this paper will be valuable in guiding this work. The committee would welcome any other similar information on available protection as well as letters pointing out weaknesses of present protection. No doubt there will be a need for much consultation with manufacturers of motors, relays, industrial control, and special protective devices such as those related to lubrication and cooling. Full co-operation will be needed since the field of exploration is unlimited. Letters should be addressed to Mr. Von Roeschlaub or to me.

John Baude: I should like to thank Mr. Barnes for his discussion which emphasizes the need for a revision of motor standards. Only complete co-ordination of motor and starting reactor standards can help to realize the benefits of modern protective and control methods, of which cage winding protection for synchronized machines is only a relatively small part.

Since the cage winding protective relay is intended to protect the motor during the relatively short time of subsynchronous operation only, the relay's operating tolerance is safely within the accuracy with which cage winding thermal capacity can be predicted. In general, it will be found that the heating cycle of this type of noncompensated relay is less affected by ambient temperature changes than the cooling cycle, and both tolerances vary with the operating periods.

Since the contact mechanism of the relay requires a definite force for operation, two bimetallic strips will help to provide this critical operating force in less time than one, and the heat generated within the heater element is more protected from radiation than it would be with a single bimetallic strip.

The incomplete function heater element *48X* in Fig. 5 was included for backup protection of the heater element device *48* in Fig. 5. The cooling time of *48X* is much shorter than of that of *48* and thus will cause no needless waiting time of the operator in case of an incomplete sequence operation.

Direct-Stroke Protection of High-Voltage Switching Stations and Transformers

THIS paper presents results of an investigation into a phase of the lightning protection problem which has not been completely evaluated in the past: that of protection against direct strokes terminating on transmission towers and conductors immediately adjacent to high-voltage stations. Lightning protection of extensive stations in the past has been based on the premise of incoming traveling waves on overhead transmission lines, the surge having originated 1 or $1^1/_2$ miles away from the station. This broad premise encompasses two basic assumptions:

1. The station structure is so well shielded that there is practically no possibility of a lightning stroke terminating on a phase conductor within the station.
2. The first mile or so of incoming line is lightningproof or, if not, the probability of a flashover is so small that equipment failures in the event of close-in strokes can be accepted as considered risks.

Recent treatments of protection against incoming traveling waves are given in three papers[1–3] covering miniature-system studies, and two papers[4,5] covering field tests.

The possibilities of obtaining direct-stroke protection of high-voltage switching stations and transformers were studied on an actual station, the St. Lawrence River Power Project, now being undertaken jointly by the New York State Power Authority and the Hydroelectric Power Commission of Ontario. It had been determined by the engineers of Uhl, Hall, and Rich and the Commission that cable leads would be advantageous for the connections from the transformer, located on the dam, to the switching stations located on the shores. It was essential that these cables, and their associated transformers be given adequate lightning protection.

With respect to transient voltages, cables behave in a manner similar to overhead lines. However, they have much lower surge impedance and inductance and much higher capacitances, and these properties are in a direction to help the problem of surge protection. These circumstances suggested to the authors that surge protection could be studied to advantage with respect to the following points:

1. Can reliable protection be obtained against close-in direct strokes?
2. How many high-voltage lightning arresters are required?
3. What is the best placement of the arresters?

These questions have been studied at length on the Anacom analogue computer. The main object of the studies was to obtain facts pertaining to direct-stroke protection of stations and transformers. With such facts available, protective features of stations can be made on a more rational basis.

Physical Layout

Differences in local conditions resulted in two different situations: On the United States side, the cables run directly from the dam to the switching station; therefore the switching station has the initial exposure to lightning surges. On the Canadian side, the cables run from the dam to the shore and thence via overhead lines to the switching station several miles remote; therefore, the cables have the initial exposure to lightning surges. These two cases are representative of conditions that may be encountered elsewhere.

In Fig. 1, the major dimensions are shown for the 6-line 4-cable bus with four transformers on which the study was made. Cable lengths were varied from 500 to 3,500 feet in length. Fig. 2 shows an approximate physical layout and a diagrammatic representation of those circuit elements pertinent to a study of direct-stroke protection. The symbols L_1, L_2, and R_1, R_2 are the inductances and resistances of the first and second towers away from the station T_1 and T_2 respectively. L_s and R_s are the station structure inductance and resistance to ground. The letter symbols of Figs. 1 and 2 are voltage measuring points and serve to orient Fig. 2 with Fig. 1.

Direct strokes are most destructive if they occur in the one or two tower spans on the outgoing overhead lines from the switching station. Ground wires in these critical spans are three in number, and have a spacing between outermost wires greater than that of the phase conductors. This gives three desirable features: low surge impedance, practically perfect

shielding, and increased coupling to the phase conductor.

Circuit constants for the transmission lines, cables, ground wires in the critical spans, and rating of the lightning arresters are given in the following section.

Circuit Constants

TRANSMISSION LINES: PHASE CONDUCTORS

Inductance per foot, 0.45 microhenrys (μh).
Capacitance per foot, 2.22 micromicrofarads (μμf).
Surge impedance, 450 ohms.
Velocity of propagation, 1,000 feet per microsecond (ft/μsec).
Line insulation, 16 standard 10 by $5^3/_4$-inch insulators.
Span length, 1,000 feet.

CABLES

1,000,000-circular-mil copper, 0.925-inch paper insulation.
Inductance per foot, 0.06 μh.
Capacitance per foot, 66.7 μμf.
Surge impedance, 30 ohms.
Velocity of propagation, 500 ft/μsec.

LIGHTNING ARRESTERS

195-kv station-type lightning arrester.
Gap breakdown for slow-wave front, 600-kv crest.
Discharge voltage, 600-kv crest at 10,000 amperes used for cases *A* and *B*; 550-kv crest at 5,000 amperes used for case *D*.

CIRCUIT BREAKERS

Capacitance per bushing, 500 μμf.

TRANSFORMERS

Equivalent surge capacitance, 1,500 μμf.

SHIELDED SPANS

L_{11} = Ground wire self-inductance per foot, 0.22 μh.
L_{22} = Phase conductor self-inductance per foot, 0.45 μh.
L_{12} = Ground wire to phase conductor mutual inductance per foot, 0.77 μh.
C_{11} = Ground wire to ground capacitance per foot, 4.55 μμf.
C_{22} = Phase conductor to ground capacitance per foot, 2.22 μμf.
C_{12} = Ground wire to phase conductor mutual capacitance per foot, 13.00 μμf.
Surge impedance of ground wires = 220 ohms.
L_1 = Tower inductance, 20 μh.
L_s = Switching station inductance, 5 μh.
R_s = Switching station resistance, 1 ohm.
R_1 = Tower-footing resistance, variable from 5 to 20 ohms, 10 ohms used in most cases.

COUPLING FACTOR BETWEEN GROUND WIRES AND PHASE CONDUCTORS

35% for cases *A* and *B*.
65% for case *C*.

Anacom Procedure

Techniques used in representing the station on the Anacom have been given in detail in the literature.[1,2] In brief, the procedure consisted of setting up on the computer the proper inductances, capacitances, and resistances to represent faithfully the transient wave response of the actual circuit elements. Multipliers for the various elements were chosen to obtain wave fronts suitable to the Anacom with respect to fidelity of response and adaptability to photography on the cathode-ray oscillograph.

Fig. 1 shows the circuit used in the study. Distributed constants of the overhead lines and cables were simulated by pi-sections as illustrated in Fig. 2(B). For simplicity, only a few pi-sections are shown; in the actual setup, a sufficient number were used to assure proper response for the wave shapes encountered. Overhead lines which were so long that reflections from their ends would not return in time to affect voltages within the station were terminated in their surge impedances (represented by *Z* on lines 2 to 6 of Fig. 1). When more than two cables were used, additional cables were represented by their equivalent lumped capacitance. Transformers and circuit breakers were represented by their equivalent surge capacitance. Circuit constants for the phase conductors, cables, and ground wires are given in the section "Circuit Constants."

A major deviation from the Anacom representation used in previous studies[1-3] was the detailed representation of coupling between ground wires and phase conductor in the one or two spans entering the station. A single pi-section of this representation is given in Fig. 3, which shows both electrostatic and electromagnetic coupling. Constants shown in the figure are calculated in a manner similar to that in reference 6.

$$C_M = \frac{C_{11}C_{22}C_{12}}{C_{12}^2 - C_{11}C_{22}} \tag{1}$$

$$C_C = \frac{C_{22}^2 C_{12}}{C_{12}^2 - C_{11}C_{22}} \tag{2}$$

$$C_G = \frac{C_{11}^2 C_{12}}{C_{12}^2 - C_{11}C_{22}} \tag{3}$$

where the symbols with numbered subscripts are defined in the section "Circuit Constants." The use of two inductances each for ground wire and phase conductor permits the representation of different self-inductances while maintaining reciprocity of mutual inductance.

The 195-kv station-type lightning arrester was simulated by the countervoltage of a battery and a switch in series. The switch simulated arrester spark-over at 600 kv for slow front waves, while the countervoltage of the battery simulated arrester discharge voltage. This discharge voltage was set at a constant value of 600 kv for strokes terminating within one or two spans from the station and at 550 kv for the strokes terminating 1 or $1^1/_2$ miles

CE-1 and *CE-2*	Voltage at cable entrances of cable 1 and 2 respectively
TR-1 and *TR-2*	Voltage at transformers located on cable 1 and 2 respectively
OCB-1	Voltage at circuit breaker located at station entrance of line 1

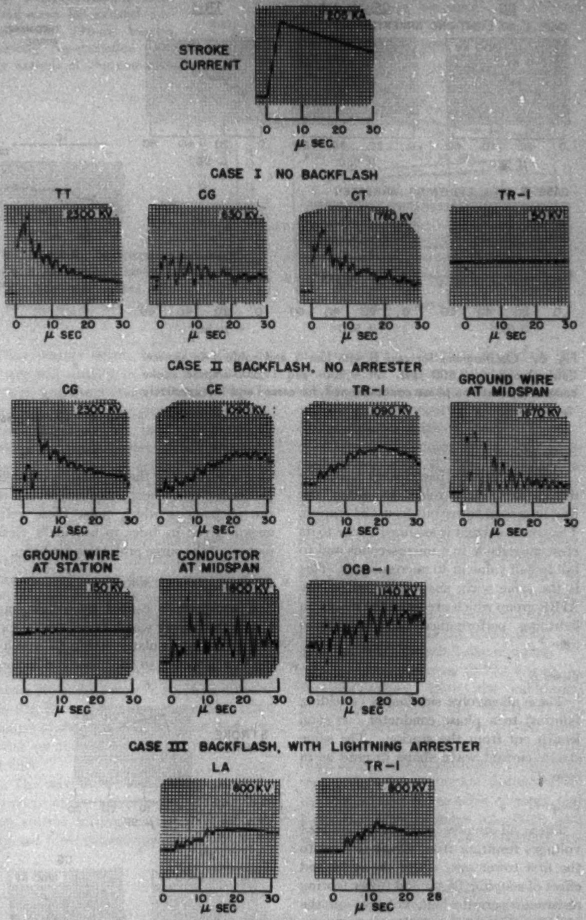

Fig. 5. Oscillograms for case A with line 1 and cable 1 in service. Cable length is 2,500 feet and struck point is first tower out from station, T_1. $R_1 = 10$ ohms

from the station. These two discharge voltages correspond to 10,000- and 5,000-ampere, 10x20-microsecond arrester discharge currents respectively. This type of arrester analogue will lead to very conservative results because the tail of the arrester voltage is held constant at the maximum discharge voltage for a long period. Fig. 4 shows the actual arrester discharge current, voltage, and volt-ampere characteristic for a discharge current of 10,000 amperes. The loop, effect in the volt-ampere characteristic causes the voltage wave to drop appreciably after crest voltage is reached. For example, at 24 microseconds, the voltage has decreased to about 57 per cent (%) of its crest value, a situation which must be taken into account in interpreting the oscillograms in those cases where the lightning arrester is connected.

Surge voltages were measured at the points identified by the letter symbols of Figs. 1 and 2. Definitions of these symbols are given in Table I. All strokes were applied to line 1 and when more than one cable was in service the entire bus was connected. Disconnects on the bus side of the breaker were open except when additional lines were simulated by closing all the switches to the surge impedance resistor *Z*.

Situations Analyzed

Since there are so many combinations of variables in the surge protection problem, a systematic appraisal of all the factors which influence the magnitude and duration of surge voltages in the station must be made. The variables are:

1. Character of the lightning wave.
2. Current magnitude in the lightning stroke.
3. Number and location of lightning arresters.
4. Number of overhead lines and cables assumed to be in service.
5. Tower-footing resistance.
6. Coupling between phase conductor and ground wires.

Character of the Lightning Wave

The idea that protection against close-in direct strokes is possible led to the selection of lightning waves based on stroke current rather than stroke voltage for study. Cases *A*, *B*, and *C*, in the following, are the three possible kinds of waves resulting from different considerations of stroke currents and the point in the system which is hit. Case *D* involves a traveling voltage wave originating some distance away from the station. The latter is the one case which has been used in previous studies[1-3] and is included here for correlation.

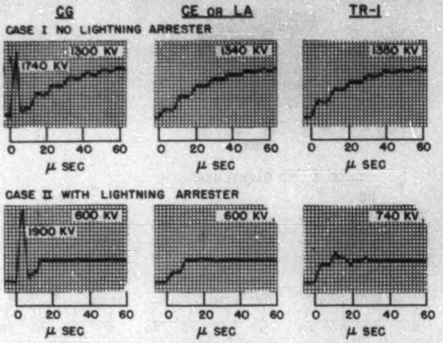

Fig. 6. Oscillograms for case B with line 1 and cable 1 in service. Cable length is 2,500 feet. A 9,200- and 11,200-ampere stroke current terminate on phase conductor at T_1 for cases I and II respectively

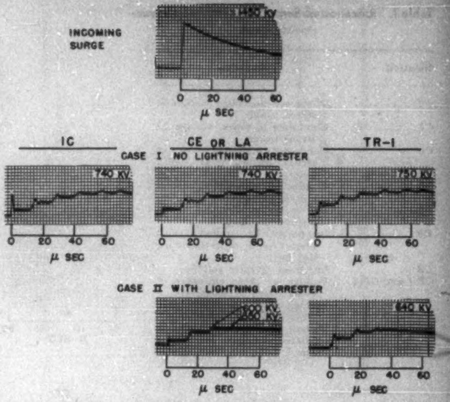

Fig. 8. Oscillograms for case D with line 1 and cable 1 in service. Cable length is 3,500 feet

Cases A

These all involve backflashes caused by direct lightning strokes to either the first or second tower out from the station. The stroke current is assumed to rise to its crest magnitude in 4 microseconds and to fall to half value in 40 microseconds. This is the same wave shape selected by the AIEE group which prepared the report on lightning performance of transmission lines.[7]

Cases B

These all involve sideflashes (shielding failures) to a phase conductor one span length out from the station. The same stroke current wave shape in used as in case *A*.

Cases C

These all involve coupled or induced voltages resulting from direct strokes to the first tower out, where the combined effect of coupling factor and tower-footing resistance permits high voltages on the phase conductors even if there is no tower-to-conductor backflash. The stroke current wave shape is the same as in case *A*.

Cases D

These all involve incoming traveling voltage waves originating 1/2 mile or so out from the station. The standard AIEE $1^1/_2$x40-microsecond wave shape[8] is used, as the most severe of the six waves used in previous studies.[1,2]

Discussion of Phenomena

Primarily, the object of the study was to obtain numerical values of surge voltages as a guide for the application of surge protective equipment. A brief review of the phenomena which cause these voltages is given in order to provide a clear picture of the surge protection problem.

Cases A: Backflashes

A backflash is caused by a lightning stroke to a tower which raises the potential across an insulator string *CT* resulting in a flashover to the phase conductor. The oscillograms of Fig. 5 show the mechanism of a backflash. After lightning strikes the tower, the tower-top potential *TT* builds up according to $L_1dI/dt+R_1I$. The first row of oscillograms in Fig. 5 shows the conductor-to-ground voltage *CG* at the struck point, the conductor-to-tower voltage *CT* across the insulator string, and the voltage at the transformer *TR-1* which would exist if no backflash occurred.

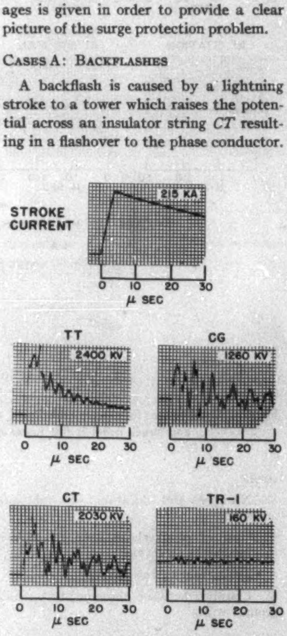

Fig. 7. Oscillograms for case C with line 1 and cable 1 in service. Cable length is 500 feet and struck point is at T_1. $R_1=10$ ohms

Depending upon the magnitude of stroke current, tower inductance, and tower-footing resistance, the voltage across the insulator string *CT* may be high enough to cause a backflash. The impulse withstand strength of the 16 insulators was determined for the particular wave form by the integration method,[1,2] which showed that 205,000 amperes are necessary to flash over the line insulation, assuming a 10-ohm tower-footing resistance. The backflash was assumed to occur at 4 microseconds, which is the point where the tower-top potential starts to decrease. When a backflash does occur, the voltage on the phase conductor *CG* rises to the tower-top potential of 2,300 kv and has the same wave shape on the tail as the tower-top potential. Shown in the second row of Fig. 5, this is the general shape of voltage waves placed on the phase conductor in all cases *A*, since L_1 and R_1 are of such relatively low impedance that the circuits connected at the station have no appreciable influence on the voltage at the struck point. Resultant voltages at other points in the station are shown in the second and third rows of Fig. 5.

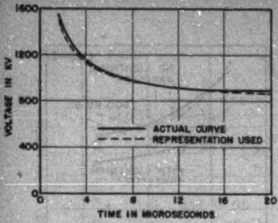

Fig. 9 (left). Impulse withstand curve for external porcelain of 196-kv bushing showing representation used for analysis of Anacom data

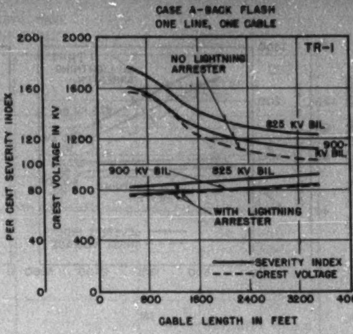

Fig. 11 (right). Stroke current of 205,000 amperes terminates 1,000 feet from station at T_1 having an $R_1=10$ ohms

Some observations from Fig. 5, while not directly pertinent to the protection problem, afford a better insight to the nature of the phenomena. Half way between the struck tower and the station, the voltage on the ground wire is highly oscillatory because of reflections from the station. But the ground wire potential at the station (actually the station steel potential) is quite low in consequence to the low ground resistance of the station. Reflections from the station and altered coupled voltage from the ground wire change the character of the traveling wave on the conductor considerably, as it moves from the struck point *CG* to mid-span and to the incoming circuit-breaker location *OCB-1*. The high-frequency components are largely suppressed by the low cable surge impedance at the cable pothead *CE*.

Also shown in Fig. 5 are the voltages at the lightning arrester *LA* and at the transformer *TR-1* with a 195-kv lightning arrester located at the cable entrance. The lightning arrester holds the crest voltage down to 600 kv at its terminals and to 800 kv at the transformer.

Cases B: Sideflashes

Sideflashes result from shielding failures which permit the lightning stroke to make direct contact with a phase conductor. They seldom occur, but when they do there will usually be a flashover to the tower, and the voltage wave entering the station will not differ greatly from that of cases *A*. However, in a few instances where the stroke current is low, the voltage may not be high enough to flash over the line insulation. These cause trouble, because they may be high enough to be dangerous to equipment insulation.

Fig. 6 shows oscillograms taken with a 4x40-microsecond current surge terminating on a phase conductor one span from the station at *CG*. Stroke current was adjusted to give a voltage at the struck point just barely insufficient to flash over the line insulation, this being the worst case. The stroke current necessary to cause flashover for the case of no arrester in Fig. 6 was 9.200 amperes, while 11,200 amperes were required to cause flashover with an arrester located at the cable entrance.

The wave shape and magnitude of the voltage at the struck point is dependent on station loading in the form of connected lines, cables, apparatus, and lightning arresters. Therefore, to obtain the same critical flashover voltage at the struck point, the magnitude of the stroke current must be varied with the number of connected circuits. Consider the case of no arresters as shown by the first row of oscillograms in Fig. 6. The voltage at the struck point *CG* initially rises at the rate of half the line surge impedance multiplied by the rate-of-rise of the stroke current. However, before maximum voltage (half the line surge impedance times the magnitude of the stroke current) is reached, a negative reflection returns from the circuit breaker and connected cable to reduce the voltage at the struck point and give the characteristic spike of voltage as seen in the oscillograms of Fig. 6. As reflections return from the cable-connected transformer, the voltage at *CG* begins to increase slowly to a second maximum value whose magnitude depends on cable length and magnitude of stroke current. Thus, for a constant distance from the struck point to the cable entrance and a constant stroke current magnitude and wave shape, the first spike of voltage has

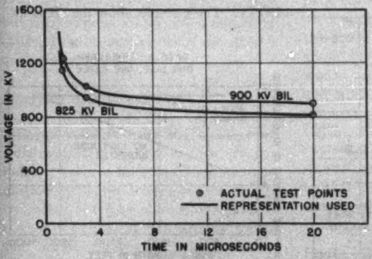

Fig. 10. Impulse withstand test points for 900-kv and 825-kv BIL transformer and curve showing representation used for analysis of Anacom data

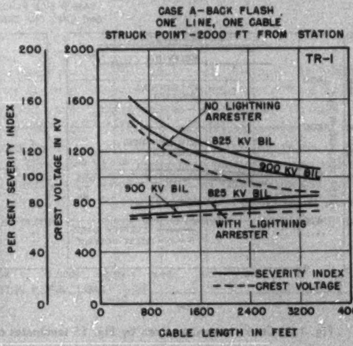

Fig. 12 (right). Stroke current of 205,000 amperes terminates 2,000 feet from station at T_2 having an $R_2=R_1=10$ ohms

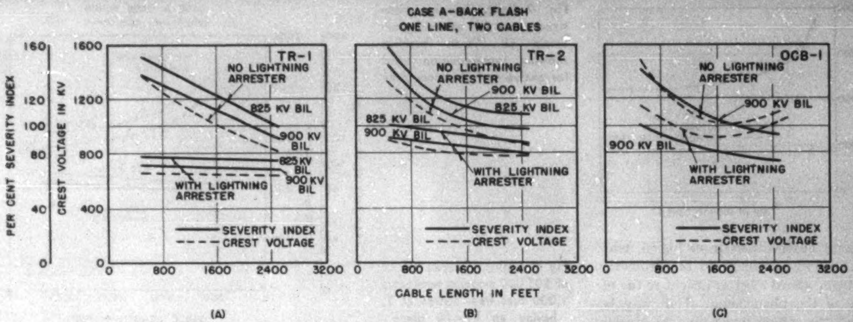

Fig. 13. Stroke current of 205,000 amperes terminates at T_1 having an $R_1=10$ ohms. The whole station bus is connected and a lightning arrester is located only at CE-1

a constant magnitude but the second slowly rising voltage magnitude and shape depend on the cable characteristics. The wave shape of this slowly rising voltage is the principal determinant of flashover since the influence of the spike of voltage is small compared with the influence of the second voltage wave. Therefore the stroke current was varied in the study to obtain the critical voltage of 1,300-kv crest for the second slowly rising voltage wave. Although this voltage varies with cable length, the variation is small and for conformity was held constant at 1,300 kv for all cable lengths.

For the case of an arrester located at the cable entrance, the first spike of voltage results from the same phenomena as mentioned for the case of no arrester. However, after this first spike, the arrester holds the voltage to approximately 600 kv, the arrester discharge voltage. Therefore, cable length has no effect on the voltage wave shape at the struck point and the wave shape of the first spike of voltage determines whether or not there is flashover of the line insulation. The critical crest voltage is 1,900 kv, which corresponds to a stroke current of 11,200 amperes.

As shown in Fig. 6, the lightning arrester analogue was set to hold 600 kv, corresponding to a crest discharge current of 10,000 amperes. As has been pointed out, the type of arrester analogue employed yields extremely conservative results with respect to the magnitude of the wave tail, and this must be considered in interpreting the voltage across the transformer *TR-1*. If a more exact analogue had been used, the shape would have been similar to the voltage wave of Fig. 4(B) with a crest of 740 kv and it would have been down to about 422 kv at 24 microseconds.

Cases C: Coupled Voltages

Coupled voltages are placed on the phase conductor by direct strokes to a tower with no backflash. These cases were studied to determine the relative severity of coupled voltages as compared to those obtained from backflashes. The Anacom set-up was exactly the same as for cases *A*, but the switch simulating the backflash was not closed. Consequently, stroke current was not applied conductively to the phase conductor; instead, stroke effects were coupled onto the phase conductor solely through the electromagnetic and electrostatic coupling shown in Fig. 3.

Surge voltage coupled on to a phase conductor *CG* for normal line constants is shown in Fig. 5, case I, and its magnitude is quite low. A more severe condition can be anticipated in which the coupling factors are increased intentionally (by aerial counterpoises) to prevent backflashes.

For the oscillogram sequence of Fig. 7, the coupling factor was increased to 65% the tower footing resistance was kept at 10 ohms, and a 500-foot cable was connected to the station. The crest stroke current of 215,000 amperes was just insufficient to cause a backflash. Crest voltage at the transformer (*TR-1*) was only 160 kv. These results show that it is un-

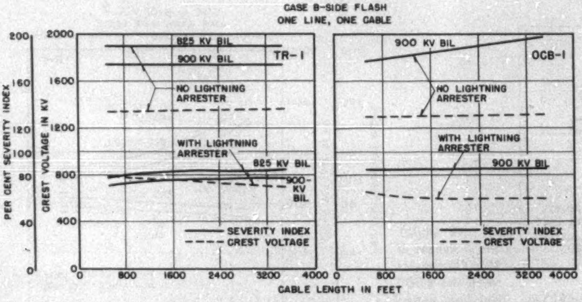

Fig. 14. Stroke current as given by Fig. 15 terminates on phase conductor at T_1

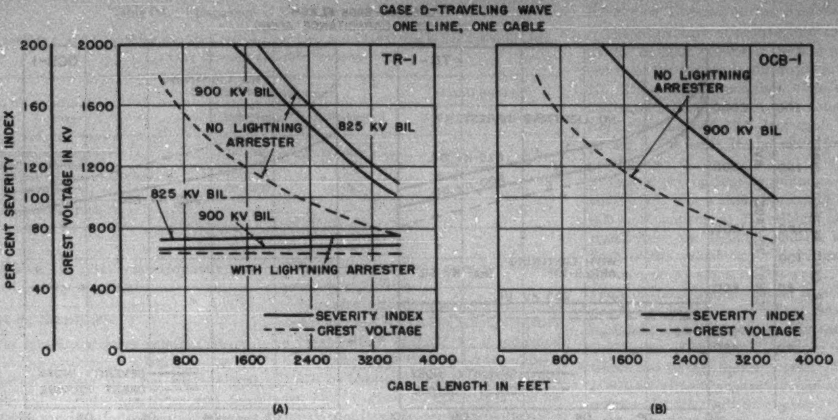

Fig. 16. Incoming surge voltage is 1,450-kv crest, $1^1/_2$x40-microsecond wave shape

necessary to consider direct strokes which do not result in backflashes.

Cases D: Traveling Voltages Waves

Studies were made of cases involving incoming traveling voltage waves to show the comparison in surge voltages caused by direct strokes close to the station and those caused by strokes some distance away. Fig. 8 shows oscillograms for the case of one overhead line and one 3,500-foot cable.

The lightning arrester was set to spark-over at 600 kv but the discharge voltage was held constant at 550 kv, which corresponds to a discharge current of 5,000 amperes. The crest voltage at the transformer *TR-1* is slightly higher than the arrester discharge voltage, but not sufficiently to alter the protection afforded. As with side flashes cases *B* the duration of arrester voltage appears to be too long, but this, as previously pointed out, is because of the characteristics of the arrester analogue employed.

Analysis of Anacom Data

Surge voltages from the oscillograms were evaluated in terms of their severity index,[1-3] a procedure based on the integration method of expressing the disruptive effect of nonstandard waves in terms of that of equivalent standard test waves. For circuit voltages of 69 kv and over, disruptive effect is given by the relation

$$\text{Disruptive Effect} = \int e^{K_2} dt$$

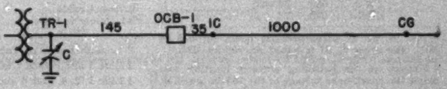
where e is the surge voltage as a function of time and K_2 is a constant. The % severity index (SI) is the ratio, expressed in %, of the crest voltage of the surge under consideration to the crest voltage of a surge of the same shape which will stress the insulation just to the impulse withstand curve. Or, to put it another way, % SI of a surge of any odd shape is the ratio, expressed in %, of the crest voltage of a reference wave having the same disruptive effect as the odd wave to the crest voltage of the same reference wave which will stress the insulation just to its impulse withstand curve.

In this study consideration was given to the disruptive effect of surges on the transformer insulation, and on the circuit-breaker insulation. SI's of surges on the circuit-breaker insulation are expressed in terms of the external portion of the 196-kv bushing having an impulse withstand curve as in Fig. 9. Any wave which will stress the bushings to this curve has an SI of 100%; for example, both a 1,550-kv, $1^1/_2$x40-microsecond wave chopped at 1.5 microseconds and a 900-kv, $1^1/_2$x40-microsecond wave chopped at 14 microseconds have SI's of 100%. Equating the expressions for disruptive effect of these two waves, the constant K_2 comes out to be 4.7 for the 196-kv breaker bushing. SI's of surges on the transformer were expressed in terms of the standard impulse withstand tests for both the 900-kv and 825-kv basic impulse insulation level (BIL) transformers. Therefore, for the 900-kv BIL transformer, either a 1,035-kv, $1^1/_2$x40-microsecond wave chopped at 3 microseconds or a 900-kv, $1^1/_2$x40-microsecond full wave have SI's of 100% on the transformer insulation. Based on these two standard test waves, the constant K_2 is 9.1 for the transformer insulation. Because the chopped-wave test is 15% higher than the full-wave test, the constant K_2 will be 9.1 for all transformers. The impulse withstand curves for the 900-kv and 825-kv BIL transformers are shown in Fig. 10. The curves were plotted from calculated values of SI and therefore they pass through the chopped-wave and full-wave test points, protection being co-ordinated on these two points.

Discussion of Results

SI's and crest voltages at various measurement points are plotted against cable length in Figs. 11 through 18. Tables II and III give additional data for multiple circuits for cases *A* and *B*. For the most part, the curves and diagrams of Figs. 11 through 18 and Tables II and III with their captions are self-explanatory. Discussion of each curve is

Fig. 17. Single-line diagram of circuit tested to show effect of adding lumped capacitor at TR-1



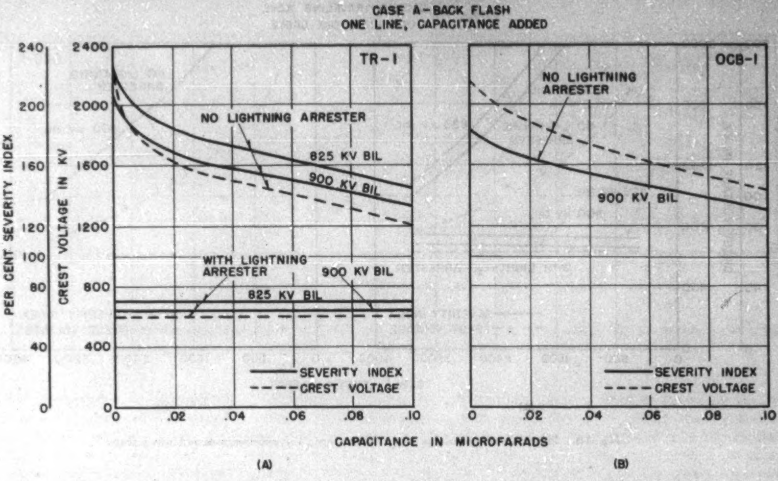


Fig. 18. Stroke current of 205,000 amperes terminates at T_1 having an $R_1 = 10$ ohms. (Refers to Fig. 17)

omitted in the interest of brevity. The curves can be used for reference purposes, and for protection problems in general. While the data are all in terms of a 230-kv system, judicious extrapolation should be possible with other operating voltages. In general, it may be expected that the SI will be higher for 138-kv systems and lower for 330-kv systems for comparable cases.

Case A: Backflash

Comparison of Figs. 11 and 12 shows that voltages at the transformer become less severe as the stroke terminating point is moved farther out from the station.

* The % SI in parentheses is based on 825-kv BIL; the other % SI is based on 900-kv BIL.

† Voltage at the lightning arrester location was below the spark-over voltage of the 195-kv arrester.

With one line and one cable connected, voltages at *OCB-1* were recorded only for a 2,500-foot cable. With arrester connected, a crest voltage of 1,200 kv having an SI of 144% appeared at *OCB-1*. With an arrester connected at the cable entrance, the voltage reached a crest of 1,150 kv and had an SI of 84%. However, protection of circuit breakers for other cable lengths can be estimated, from the curves of Fig. 13(C) which apply where two cables are in service. Assuming the same shape curve as in Fig. 13(C), the SI at *OCB-1* for one 500-foot cable and an arrester is 113%. The 100% SI point occurs at a cable length of 1,000 feet. Therefore, it is estimated that for case *A*, with one line and one cable, the breaker is protected for cable lengths longer than 1,000 feet.

Surge voltages at transformer *TR-2* shown in Fig. 13(B) apply for the case of an arrester located at the cable entrance *CE-1* and nowhere else in the station. Adequate protection might be afforded transformer *TR-2* for some cable lengths, depending on the transformer BIL. However, in the actual station it is desirable to place an additional arrester at *CE-2* so that protection of *TR-2* is assured if a backflash should occur on line no. 2. In this case, the curves of *TR-2* would be identical to those of *TR-1*.

foot cable, the station is adequately protected without arresters.

Case B: Sideflash

The severity of surge voltages appearing at the equipment is less than for the backflash of case *A;* see Fig. 14 and Table III. With four lines and four cables in service, the station is protected without arresters; see Table III. If flashover to the tower at the struck point does occur, the severity of surge voltage at the apparatus is greatly reduced; see Table IV.

Case D: Traveling Voltage Wave

The significant fact for Fig. 16 is that the SI of surges at the transformers with an arrester in service is lower for case *D* than for cases *A* and *B*.

Effect of Capacitance in Reduction of Surge Voltage

The picture would not be complete without some calibration to the effect toward reduction of surge voltages exerted by the cable circuits. For this purpose, data for case *A* were taken on the circuit of Fig. 17, which is the same as Fig. 1 from point *CG* to *BI*, capacitance being added at point *TR-1*. These data are presented in Fig. 18 which shows that the presence of high-voltage cables makes direct-stroke protection possible.

For zero added capacitance (i.e., an open line) and with no lightning arresters, a crest voltage of 2,350 kv is indicated. Comparing the 2,350 kv with the value of 1,570 kv obtained with 500 feet of cable, see Fig. 11, gives an example of the improvement from the presence of the cable. A 500-foot cable has about 0.033 μμf capacitance. Reading from Fig. 18, a crest voltage of 1,570 kv is obtained for this value of capacitance, which checks the value from Fig. 11, taken with pi-sections representing the distributed constants of the cable.

Comparison of Voltages at Ends of Bus

Fig. 19 shows a comparison between the bus voltages at the incoming line bay *BI* and at the most remote point from the incoming line bay *BR* for case *A* with a 205,000-ampere stroke to T_1 having a 10-ohm footing resistance. One line and two 2,500-foot cables were in service for these oscillograms, which show that the crest voltage at *BR* is 20% higher than the voltage at *BI* for the case of no arrester. For an arrester connected at *CE-1* the crest voltage at *BR* is 14% higher than the voltage at *BI*.

Effect of Tower-Footing Resistance

The importance of securing low tower-footing resistances *TFR* at the first tower out from the station is illustrated in Fig. 20. These oscillograms show voltages at the transformer for cases *A*, with one overhead line and one 2,500-foot cable connected. The scale is the same for all oscillograms.

Two stroke current magnitudes were considered. For a stroke current of 145,000 crest amperes at T_1, voltages at the transformer are negligible until a backflash occurs, which is for a footing resistance of 20 ohms in this case. The value of the lightning arrester in holding down the transformer voltage when a backflash occurs is illustrated in the last oscillogram of the case I sequence which shows two voltage traces: a crest voltage of 970 kv without an arrester, and a crest voltage of 760 kv with an arrester.

The case II oscillograms of Fig. 20 were made with the same setup as case I except that the stroke current was 205,000 amperes, a value just high enough to cause a flashover with a 10-ohm tower-footing resistance. It is significant that the highest stroke current ever recorded in the field measured only 218,000 amperes. This leads to the conclusion that there is practically no possibility of a backflash occurring if the tower-footing resistance is 10 ohms or less. The effect of the lightning arrester is also shown on the last two oscillograms of the sequence.

Comparison of Cases

In terms of the surge voltages which have the highest severity on the transformer insulation, Fig. 21 shows a summary of the "worst" examples for the four general cases studied. In each case line 1 and cable 1 were in service and the stroke terminated on T_1 which had a footing resistance of 10 ohms (except case *D*,

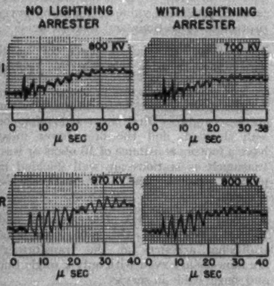

Fig. 19. Oscillograms comparing surge voltages at BR and BI

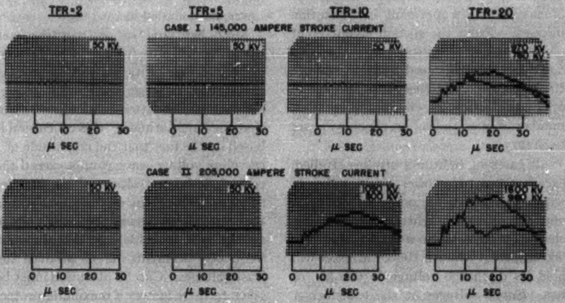

Fig. 20. Oscillograms of transformer voltages for various values of tower-footing resistance TFR

the traveling wave). The oscillograms show that the highest voltages occur for case *A* while cases *B* and *D* are of lesser severity. Case *A* is approximately 30% higher in crest voltage than case *D* which has been the commonly accepted criterion. Case *C* is of such low magnitude that it need not be considered in surge protection studies.

Analysis of Results

Data taken during the study permit a very complete assessment of lightning protection for 230-kv stations. However, a reasonable basis for station protection design must be selected from the wide range of cases studied, and due consideration must be given to certain premises. These premises are: 1. Effective shielding is provided for the switching station and on each overhead line in the one span immediately adjacent to the station through the use of three ground wires. 2. Footing resistance of the first tower out from the station is 10 ohms or less. 3. The station ground resistance is less than 1 ohm. 4. Lightning arresters are located at the cable potheads.

Strokes beyond the first span must fall in the categories of sideflashes or backflashes. In either case, the SI of the conductor-to-ground voltage wave may not exceed the line insulation strength. In the studies of cases *B* and *D*, this relation is established, and it may therefore be concluded that only the first span must be given 100% shielding, and only the first tower a low-footing resistance. Stated another way, the inductance of one span limits the incoming surge energy to protectable values.

With all lines and cables in service, the station is inherently self-protected from lightning without any lightning arresters. However, as the number of lines and cables in service is reduced, the magnitude of surge voltages appearing in the station increase. From the station layout point of view, the most critical case is that of a single outgoing line and a single cable to the transformer. Hence, it is prudent to apply protection based on the smallest number of lines and cables which will ever be in service.

All cases of lightning strokes studied, except those to a tower or ground wire with no backflash, are potentially dangerous. In all cases, lightning arrester discharge currents are in a zone (below 12,000 amperes) where a 195-kv arrester will hold its discharge voltage to 600 kv, or less. Surge voltages at the transformer exceed the arrester discharge voltage by a small amount, dependent upon the length of cable, the stroke current magnitude, and the character of the lightning wave.

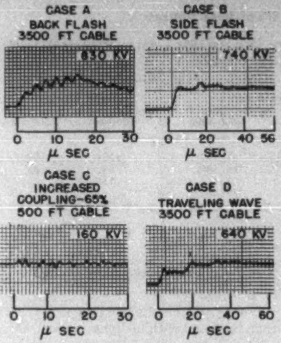

Fig. 21. Oscillograms showing summary of worst cases of surge voltages at transformer TR-1

With respect to surge voltages at the transformers, consider the shielding failure (cases *B*). On a probability basis, it is the least likely to occur. It requires a shielding failure (probability in a given span of about 1 in 5,000 years) and a stroke current in the limited range of 5,000 to 11,200 amperes (probability about four in 10) to require consideration. Thus, the over-all probability is placed at perhaps once in 10,000 years, odds which are too great to merit consideration.

Direct strokes followed by a backflash at the first tower out from the station (cases *A*) are highest in order of severity. Probabilitywise, the chances of the first tower being struck are small compared to strokes on several miles of line. However, protection against these strokes is possible when using cable connections to the transformers, so surge voltages originating from direct strokes to the first tower are included in the picture.

Most lightning surges meriting consideration will arise from strokes to towers or ground wires within about 10 miles of the station. Surges traveling a greater distance will be attenuated to an extent that they are harmless; this conclusion is based on the fact that the magnitude of a traveling voltage wave cannot exceed the critical flashover voltage of the line insulation. The point of this discussion is that strokes producing the most voltage are the least probable, and that the most frequently occurring surges produce the least voltages. Careful attention must be given to these factors if maximum protection is to be attained at minimum cost.

Figures of SI for the worst cases from Figs. 11, 14, and 16 are shown in Table IV, in which transformers with 825-kv or 900-kv BIL are shown as adequately protected for all cases considered with a 195-kv arrester located at the cable entrance. If 185-kv arresters are used, the protection margins in the case of 825-kv BIL is established as approximately as good as for 900-kv BIL with 195-kv arresters.

Circuit-breaker data are not available for the traveling wave (case *D*). However, because traveling waves produce less severe voltages than cases *A* or *B* at the transformer, it can be assumed that the same phenomena will apply at the circuit breaker. Therefore, the circuit breaker is adequately protected except for case *A* with short cable lengths. The 100% SI point for this case has been estimated to occur at a cable length of 1,000 feet. Therefore, except for cable lengths under 1,000 feet, the circuit breaker is adequately protected in all cases. If an 825-kv BIL transformer is used with an 185-kv arrester, it is reasonable to assume that the severity of the voltage wave at the 900-kv BIL circuit breaker will be low enough that the breaker will be protected for all cable lengths for all cases studied.

One of the most significant conclusions to be drawn from Table IV is that the severity of the surge voltage at the transformer produced by the worst case considered (case *A*, backflash) has an SI only 7% greater than the surge voltage produced by the traveling wave (case *D*). This leads to the conclusion that the traveling wave produces voltages only 7% less severe than the worst of close-in direct strokes, provided, of course, that the prescribed measures are taken for direct-stroke protection.

Conclusions

1. Use of cable leads to the transformers is of considerable value in lightning surge protection of stations and transformers.

2. Because of the presence of cable capacitance, reliable direct-stroke protection can be secured.

3. To secure direct-stroke protection, the stations and the first span out must be well shielded, and the first tower must have a footing resistance of 10 ohms or less. Inasmuch as stations are well shielded in present practice, the additional expense is small.

4. With 900-kv BIL transformers and 195-kv arresters at the cable entrances, additional arresters at the transformers are unnecessary even with only a single line and single cable in service.

5. With 185-kv arresters at the cable entrances and transformers of 825-kv

BIL the transformers are adequately protected, without additional arresters at the transformers.

6. When the direct-stroke protection problem is recognized and provided for, the surge voltages are only 7% more severe than those from traveling waves.

7. The circuit breaker with 900-kv BIL on the incoming line is adequately protected, provided a lightning arrester is used at the cable pothead and the cable length is longer than 1,000 feet. For the most severe strokes, the line circuit breaker may not be protected if there is only one cable and it is less than 1,000 feet long. However, the probability of strokes as severe as those studied is exceedingly remote. In any specific case, these factors should be evaluated in determining what protection should be provided.

8. Lumped capacitors, if large enough, can afford benefits similar to those afforded by cables, and the influence of capacitors, for power factor correction or other purposes, should be considered in the lightning protection problem.

Discussion

E. Beck (Westinghouse Electric Corporation, E. Pittsburgh, Pa.): The paper shows how the risks of damage from severe direct strokes can be reduced to a virtually negligible quantity. When the authors speak of the "idea that protection against direct strokes is possible" I do not think they mean that past practices have not provided protection; they are speaking of degrees of protection and degrees of stroke current.

Certainly protection has been afforded against direct strokes into and close to substations, even unshielded ones, in the past. Lightning-arrester engineers, as far as we are aware, have not hesitated to declare that adequate arresters applied at apparatus terminals will protect for the great majority of strokes, perhaps for all but those catastrophic strokes that occur about as often as earthquakes.

Experience bears this out. There are many unshielded stations. It is estimated that a small substation might be struck once in 10 to 15 years. Thus 1 in 10 or 15 might be struck each year. We doubt that in such substations the failure rate of protected transformers is 7 to 10%, or even half of it. A look at distribution transformers gives a similar picture. Direct strokes close to distribution transformers are quite likely and many must have occurred during the past 30 years.

The authors have shown how a cable-connected transformer can be protected against very severe strokes with arresters only at the cable entrance and not at the transformer, thereby giving protection also to the cable and adjacent switchgear. The beneficial effects of cable are effectively demonstrated. The benefit to the switchgear is important. Therefore, the paper is a contribution to the lightning protection art.

W. S. Price (American Gas and Electric Service Corporation, New York, N. Y.): Protection of station equipment against surges caused by lightning strokes adjacent to the station should be based, first, on the probability of such surges occurring, and second, on the probable severity of such surges when they do occur. Heretofore, it has been assumed that transmission lines would be so well shielded and would have such low tower-footing resistances for 1 mile out from a station that neither shielding failures nor backflashes would occur in this area. Although this assumption may be correct, a complete appraisal of the station protection problem should include a study of the severity of surges produced in the station in case a shielding failure or backflash does occur near the station. In this excellent paper the authors have, for the first time, provided a detailed picture of the severity of such surges, and have thus partially closed an important gap in our knowledge of station lightning protection.

It is evident from the oscillograms in this paper that the high-voltage cables have a profound effect on surge voltages within the station, and their presence makes direct-stroke protection possible. However, insufficient data are presented to evaluate the protection afforded by multiple lines in a station without high-voltage cables. Possibly, a similar study could be made in the future for the benefit of those of us who do not have high-voltage substation cables.

The analogue computer studies which the authors and their associates have made in the past several years have been of great value in the application of station lightning protection on a rational basis. A secondary but worth-while benefit which I have derived from these studies is the clear picture which they have given of the life and death of a surge voltage which has entered a substation containing multiple reflection points. The textbooks tell us that lattice diagrams can be used for this purpose. However, I have never seen a lattice diagram outside of its natural habitat, the textbook, and their value to protection engineers is somewhat doubtful.

Of particular interest in this respect are the oscillograms in Fig. 5 showing the mechanism of a backflash at a struck tower, and the oscillograms in Fig. 6 showing the effect of multiple reflections in the cable.

H. M. Ellis (Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada): The authors have done an excellent job of simulating the circuitry of the St. Lawrence Power Project on the analogue computer and have very capably demonstrated the usefulness of the computer in determining the severity of voltage surges which can arrive at the 230-kv cables and transformers.

Having determined the direct-stroke currents to the transmission lines which produce excessive surge voltages at the cables and transformers, perhaps the next step should be to determine the frequency of occurrence of these overvoltages. On the Canadian side a lightning outage on the several miles of transmission line between the 230-kv cable entrance and the switchyard will mean loss of one-quarter of the generation; hence, it is desirable to obtain low tower-footing resistances on the lines, i.e., 5 ohms or less, to minimize the frequency of these outages. Based on this low resistance and good overhead shielding, the lightning outage probability and the frequency of operation of the lightning protective devices at the 230-kv cable entrances becomes approximately one every 30 to 40 years for all four single-circuit lines.

Based on the infrequent operation of the lightning protective devices, the fact that there will generally be a line outage associated with this operation regardless of the type of protective device used, and the fact that the cable significantly reduces the rate of rise of the voltage surge, it appears that co-ordinating gaps located at each end of the 230-kv cables would provide adequate protection for the cables.

H. A. Cornelius (Commonwealth Edison Company, Chicago, Ill.): A paper which explains how currents so much larger than can be obtained on the basis of traveling-wave theory can reach substation equipment has been needed for several years. The authors are congratulated for recognizing this need and for supplying some helpful information. There are a few points, however, on which additional information would be useful.

It is interesting to compare the 51-kiloampere-(ka)per-microsecond rate of rise of current to a crest value of 205 ka assumed in this paper with the comments on a 1953 paper[1] for advocating the use of a 5-ka-per-microsecond 5-ka-crest current for co-ordination purposes. One discusser stated: "No record of an arrester discharge of this character has been obtained on a line properly equipped with ground wires, nor on substations with adequate provisions for shielding. It would therefore appear that for systems having a voltage of 100 kv or greater (and shielded line conductors) the steep current discharge can be neglected." Since probability calculations, based on the simultaneous occurrence of a 5-ka rate of rise to a 5-ka crest current, show that less than 1% of the currents discharged through arresters in stations to date exceed these values, how do the authors justify the use of a 51-ka rate of rise to a 205-ka crest current?

Furthermore, are not probabilities being "pyramided" unreasonably to assume the simultaneous occurrence of such unusual things as: 1. a lighting stroke which terminates on a line one or two spans out from a substation; 2. the occurrence of almost the maximum lightning current ever recorded to any object (205 ka versus 218 ka); and 3. a shielding failure, on a line having the almost perfect protection provided by three shield wires?

There are numerous 220-kv transmission lines in service equipped with two shield wires, which have such a good performance record that describing them as lightning-proof is justified. For example, on a 160-mile long line with which I am familiar nine tripouts due to lightning have occurred over a 15-year period. With such typical experience, is it not too improbable to consider seriously that a shielding failure could occur on an even better protected line?

In the section entitled "Circuit Constants" the 220-kv tower inductance was assumed to be 20 μh. This inductance value for steel towers has been used in several other papers. The basis used to determine this value has not been stated in this or the other papers. It would be of value to have the authors state how they obtained this value. Also, have any tests been made to measure the potential at the top of a typical 138-kv or 220-kv steel tower, when subjected to, say, 5 ka per microsecond or larger rates of rise of current?

In case A of section on "Discussion of Phenomena" it is stated that a 205-ka stroke to a tower having a footing resistance of 10 ohms will cause flashover of a 16-unit insulator string in 4 microseconds. The coupling factor given elsewhere is 35%. Published 1.5x40-microsecond positive wave test data give the flashover kv of a 16-unit (10 by $5^{3}/_{4}$) insulator string as 1,660 kv. Substituting values in the normal equation used to determine the current required to cause insulation flashover when the footing resistance is low

$$\text{Tower current to cause flashover} = \frac{\text{insulation flashover kv}}{\text{tower-footing resistance} \times (\text{1-less coupling factor})}$$

A value of 254 ka was obtained. Since the paper gives 205 ka, apparently some other factor has been included by the authors. An explanation will be appreciated.

Since the shielding studied in the paper extends out only 2,000 feet, it is assumed that the authors consider this adequate. There is a question as to how much line is required for its full surge impedance to become effective. A discussion of the limits which affect this problem would be helpful.

The effect of having various numbers of lines in parallel on the 220-kv bus at the time a stroke occurs to one of the lines, on the voltage imposed on one of the transformer banks, was not stated on the paper. Perhaps the authors have this information available.

REFERENCE

1. USE OF 10x20 CURRENT WAVES FOR LIGHTNING-ARRESTER TESTS, H. A. Cornelius. *AIEE Transactions*, vol. 72, pt. III, Oct. 1953, pp. 895–901.

E. C. Wentz (Westinghouse Electric Corporation, Sharon, Pa.): The authors seem to have used the SI idea with proper caution in this paper and other papers, but I think that it is well to point out its limitations. The integration-of-voltage idea is based on the assumption that the strength of insulation varies with the time of application to conform to volt-time curves drawn through the American Standards Association full-wave and chopped-wave points. Certain independent studies purport to show that insulation strength both of air and of oil-impregnated pressboard follows this rule.

Actually the relation between voltage and time to breakdown is not entirely a function of the insulating material; it is also a function of the shape of the electrodes. In general, the streamers which initiate breakdown take a long time to propagate if they start from an edge or a point such as a coil edge or lead, and lead off into regions of weaker electric field, but they initiate flashover in a small fraction of a microsecond if they start from a large rounded surface such as a large ball on the inner end of a bushing.

Insulation, of course, must be designed to meet the chopped-wave test. Insulation over edges and points will probably be weaker when longer-time voltages, such as full waves, are applied, and the designer is careful to add extra insulation to make sure it stands the full wave. Insulation over large surfaces is probably just as strong at full waves as it is at chopped waves. So if the assumption is made that the volt-time integration indicates severity, the result will be conservative for times longer than the chopped wave.

However, at times shorter than the chopped-wave value, the insulation on many broad surfaces may break down at very little higher voltage than the chopped-wave value. There is nothing in the American Standards Association Standards to tell the designer that he should make the insulation stronger at times shorter than the chopped wave. Certainly, there is nothing to tell the designer that the insulation must meet the requirements of the SI idea, and the hope that he will be careful to meet these requirements could conceivably result in disaster.

The National Electrical Manufacturers Association steep-front test values are positive points at shorter times, and if the SI idea includes these points as a base, and if all transformers are designed and tested to these steep-front values, the SI idea will be valid down to the steep-front times—no lower.

Fortunately, the applications of the SI idea have generally been at times longer than the chopped-wave values, and, as such, are conservative. I would like to ask the authors if the number of times that insulation performance at times shorter than chopped-wave times is of great enough importance to seriously limit the application of the SI idea according to the reasoning given here. From what I can read in this and similar papers there is very little data to justify steep-front tests; I would like to have the authors' comments.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The authors have again presented a very thorough study of the lightning protection of stations. I agree with them that a low ground resistance at the first tower and good shielding will be very beneficial in keeping lightning arrester currents low, and will help greatly in maintaining good protective margins in the stations. I recommended this in a discussion[1] some years ago. The title of the paper, it seems, is a little misleading because the direct-stroke protection of stations has been in practice for many years. The authors' real intent is to make the protection possible with a minimum of lightning arresters. This they propose to accomplish by means of cables. A cable of low surge impedance and terminated by a small capacitance acts inherently as an oscillatory circuit when excited by repeated reflections over the 1,000-foot line between the tower and the station. Thus, to use the same terminology as the paper, the voltage at the *TR* (transformer) end is about twice as great as at the *CE* (cable entrance) end until the internal cable reflections occur.

In such an oscillatory circuit the resulting *TR* voltages as compared to the *CE* voltages depend greatly on the conditions of the test circuit and the current wave applied. While the authors have chosen a tremendously high current, they have also used an unusual wave form—a straight rising front and a straight falling tail. Thus, at the instant of current crest, the inductive component of the tower voltage wave of the order of 1,000 kv suddenly collapses at the very moment when the insulators flash over. This places a very short spiked traveling wave on the conductor. Because of this short spike the voltage at the *TR* end does not exceed the voltage at the *CE* end greatly and the voltage at both ends does not rise faster so that arrester action does not occur until reflections from the *TR* end reach the cable entrance.

The resulting cable and transformer voltages depend not only on the selected current wave shape but also on the ground wire condition. Thus, with three shield wires between the station and the first tower and only one shield wire beyond the first tower, the tower voltage wave would be maintained at a higher level and for a longer time, resulting in a higher ratio of *TR* to *CE* end voltages.

Of some importance are the changes in oscillograms when the lightning arrester is applied. The wave shape at *LA* (Fig. 5) appears to be considerably modified before the arrester sparks, when compared to the voltage at *CE* without arrester sparking. However, the wave at the *TR* end appears to be exactly alike in both cases.

From the text and the conclusions, one could almost deduce that shielding is needed for only the first tower. It can be shown readily that currents of the order of 50,000 amperes and ground resistance of 30 ohms (and higher currents with correspondingly lower ground resistance) can produce severe conditions in the station if ground wires are omitted at the second tower. In that case, the ground wires do not reduce the tail of the resulting voltage wave, and also currents in excess of 20,000 amperes can flow in the lightning arrester.

The authors state that the case of a sideflash to a conductor, resulting in flashover of the insulator string, will not differ greatly from that of a stroke to a tower. This is not quite true for two reasons: First, the total current required to produce high voltages in the station may be considerably less. Second, the reflection phenomena begin in the cable with a slowly rising front and are more effective in raising the cable voltages. For instance, the wave at *CG* (Fig. 5) producing the transient in the station has about a 1,200-kv crest and a 15-microsecond tail equivalent to a tower current of 120 ka. Such currents have been measured. Since the current is building up simultaneously with the traveling phenomena on the ground wire and the conductor, the tail length will likely be greater with consequent increase in cable voltage. Also, the sudden drop in voltage due to the sudden change in rate of rise of the current wave will not occur.

For all these reasons, it is doubtful that omission of an arrester at the transformer is justified for the longer cable lengths. Before such general conclusions can be drawn, it would be necessary to conduct tests with different types of current waves for the various surge conditions as outlined in this discussion.

S. B. Griscom, J. K. Dillard, and A. R. Hileman: The remarks of Mr. Beck and Mr. Price re-emphasize and clarify some of the pertinent points covered in the paper. A complete understanding of these points is essential in applying the data to station protection problems. Dr. Ellis' deductions relative to the frequency of operation of protective devices are very interesting and corroborate the marked influence of cables on station protection. We are grateful to these discussers for these observations.

Mr. Cornelius asks about the rate of rise of stroke current. The 4x40-microsecond current wave shape used in the study is consistent with reference 7 of the paper. However, this rate of rise is not present at the arrester location at the line-cable junction. Fig. 5 shows that the rate of rise of voltage at the arrester location is 50 kv per microsecond for a backflash and Fig. 6 shows a rate of rise of 45 kv per microsecond for a sideflash. Also, for the incoming traveling wave of Fig. 8, the rate of rise at the arrester location is only 18 kv per microsecond. For such low-voltage rates of rise, arrester current rates of rise are very low. However, to be conservative, the arrester discharge voltage used in this study is based on the standard test current wave of 10x20 microseconds.

Very severe conditions were assumed for this study, as Mr. Cornelius suggests. The idea was not to recommend that protection always be based on such severe assumptions; rather it was to show that if adequate protection is provided against conventional traveling waves then it is both possible and practical in some situations to protect against severe close-by strokes.

The 20-μh tower inductance is a calculated value for a 100-foot tower (ref. 7 of the paper). It was estimated from recent high-voltage surge tests (ref. 4 of the paper) that a 100-foot tower has an inductance of about 10 μh. The towers considered here are higher than 100 feet and the value of 20 μh was chosen to be conservative and to be consistent with previous studies.

The stroke current required to cause flashover cannot be calculated from the equation given by Mr. Cornelius or from the one in reference 7. These equations assume that the coupled voltage on the phase conductor is of the same wave shape as the tower-top potential and that these two waves can be arithmetically subtracted to obtain the voltage across the line insulation. This is true at some distance out on the line from the station, but immediately adjacent to the station the coupled voltage wave will be reduced by reflections from the station. The wave shapes of the tower-top potential and coupled phase conductor voltage are different and therefore can not be arithmetically subtracted. This factor was recognized and provided for in this study. For the first time, a detailed representation of the ground wire and phase conductor, Fig. 3, was included with the station equivalent circuits so that protection against close-in direct strokes could be evaluated. Fig. 5, case I, shows the tower-top potential of 2,300 kv. The coupled voltage on the phase conductor *CG* starts to rise to a voltage of the coupling factor of 0.35 times the tower-top potential or 805 kv. However, before crest voltage of the coupled wave is reached, a negative reflection returns from the station due to the decrease in ground-wire current and station loading. Thus, as seen from Fig. 5, case I, the voltage is decreased to 630 kv and the wave shapes of the tower-top potential *TT* and the coupling voltage *CG* are different. The oscillogram of *CT* shows the resultant voltage across the insulators. For this specific wave shape, the critical magnitude so as to just cause flashover was determined by the integration method to be 1,780 kv. To obtain this voltage across the line insulation, a current of 205,000 amperes is necessary.

A transmission line possesses a surge impedance which is independent of line length. In some cases where the length is short and the front of the wave is long, reflections back and forth on this line tend to wipe out the surge impedance and, for purposes of analysis, the line can be considered as an inductance. For example, in many studies of allowable separation distance between an arrester and transformer, the drop lead to the lightning arrester of about 35 feet has been shown to be adequately simulated by its inductance. Each case must be considered separately.

Regarding the effects of multiple circuit on the reduction of surge voltage within the station, these are shown in Tables II and III and Fig. 13.

Mr. Wentz's discussion of insulation and insulation breakdown is welcomed because it shows that the SI method of analyzing nonstandard surge voltages is basically sound. This method is based on the assumption that all of the test waves are equal in severity. Although the constant K_1 is determined by equating the disruptive effect equations for the chopped wave and the full wave, Fig. 10 shows that the calculated withstand curve also coincide with the front-of-wave test point. Thus, the SI method is valid over the whole range. Most surge voltages which have appeared at the equipment terminals in this and previous studies have shown the wave shape to resemble chopped waves or full waves. Therefore, front-of-wave tests hardly appear to be justified.

The stroke current analogue used is the same as employed in previous studies and it is noted from this circuit that both the front and tail of the wave are expotential in form and not straight rising front and tail as Mr. Hagenguth concluded by looking at the oscillograms. His objection to the sudden drop in voltage at the struck tower immediately after crest is reached on the tower-top potential wave is not clear. The tower-top potential is composed of a tower inductive component and a tower-footing resistive component which are modified by reflections from adjacent towers. Immediately previous to current crest the tower-top voltage is a maximum; however, at crest current the inductive component must be zero since the rate of change of current is zero. Thus, at this point the voltage drops sharply.

Mr. Hagenguth intimates that we have chosen stroke-current wave shapes that are favorable to the protection of the transformers. Actually the reverse is true; the wave shapes and current magnitudes were intentionally chosen to produce the greatest possible transformer voltages for the particular situation investigated. In particular he apparently objects to situations wherein the inductive component of the tower voltage wave suddenly collapses at the moment the line insulators flash over. Now this is a necessary circumstance in order to impart maximum energy to the line conductors with a backflash, as examination of cases I and II of Fig. 5 shows. Compare *CG* for cases I and II. Flashover does not occur in case I and the maximum conductor voltage *CG* is only 630 kv. Flashover occurs in case II and results in a crest voltage of 2,300 kv on the line conductors. Case I may be considered as having a stroke current of 205,000 amperes and case II of 206,000 amperes.

The spikes referred to could be minimized with respect to the tail of the wave by increasing the tower-footing resistance. Since one of the main objects of the paper was to demonstrate the effectiveness of low-footing resistance, low values were used in most tests. As a matter of fact, the mechanism of protection in these cases is essentially that of limiting magnitudes by a lightning arrester and filtering ripples by the cable capacities. As Mr. Hagenguth points out, with a 30-ohm tower-footing resistance, the wave tail is greater and the protection reduced.

We do not agree with Mr. Hagenguth's observations with regard to sideflashes. The sequence of oscillograms for Fig. 6 was for 9,200 amperes stroke current and the wave at *CG* is just short of being sufficient to cause flashover. A slightly higher current would have caused flashover, eliminating the tail of the wave and giving much lower voltage throughout the station.

From the oscillographic records and resultant analysis of the voltage waves at the equipment terminals, only the first span out from the station and the station itself must be well shielded to protect the station equipment adequately against sideflashes. This is shown by Fig. 14. However, the remainder of the line should be shielded to prevent line outages.

Mr. Hagenguth expresses the opinion that more tests are required to sustain the conclusions of this paper. We believe that, we have used sufficient wave forms. Upward of 1,000 oscillograms were taken in the process of determining the "worst cases."

Measurement of Resistance and Reactance of Expanded ACSR

Synopsis: A convenient method for the measurement of reactance and resistance of aluminum cables steel reinforced (ACSR) has been used and found to be accurate. The equipment and testing method are used to obtain accurate information concerning the a-c characteristics of all sizes of ACSR up to high values of current density, but the first use was to measure the impedance characteristics of expanded ACSR.

Expanded ACSR, 1.60 inches diameter, 1,275,000 circular mils (CM), has been found to have a d-c resistance of 0.0717 ohm per mile at 25 degrees centigrade (C), a ratio of a-c to d-c resistance of about 1.015, and a reactance at 60 cycles per second (cps) at 1.0-foot spacing of 0.347 ohm per mile per conductor. This reactance value corresponds to a geometric mean radius of 0.690 inch, or 86.2 per cent of the nominal conductor radius.

Expanded ACSR, 1.75 inches diameter, 1,414,000 CM, has been found to have a d-c resistance of 0.0660 ohm per mile at 25 C, a ratio of a-c to d-c resistance of about 1.015, and a reactance at 60 cps at 1.0-foot spacing of 0.337 ohm per mile per conductor. For this conductor, the reactance value corresponds to a geometric mean radius of 0.747 inch, or 85.4 per cent of the nominal conductor radius.

BECAUSE of the presence of the steel core in ACSR, data on the electrical charactersitics of such conductors are somewhat difficult to calculate. Data now published were based on the results of two series of measurements made by Prof. W. R. Work, the first about 30 years ago and the second a few years later. Originally W. Nesbit,[1] and later W. A. Lewis and others, made many of the calculations, using Prof. Work's test results, to complete the tables of electrical characteristics of ACSR which have been in use for some time. Prof. Work's tests were of a relatively small number of sizes of conductor, over limited ranges of current density, and much of the information in the published tables was obtained by interpolation and extrapolation. The magnetic and electrical properties of the steel core wire manufactured at the time of the tests by Prof. Work were possibly somewhat different from those of core wires manufactured today.

The electrical characteristics with which this paper is concerned are the reactance and effective resistance of cables at the frequency of 60 cps. The effective resistance is referred to throughout as a-c resistance.

To obtain accurate data on reactance and a-c resistance of ACSR as manufactured now, having standard strandings and over wider ranges of current densities than those for which data are now available, suitable laboratory equipment and a measurement method have been needed. In addition, the equipment and method are of value for determination of impedance characteristics of ACSR of special strandings.

Suitable equipment for such measurements was put into service in 1950 at the Electrical Conductor Laboratory of Aluminum Company of America. This paper describes the equipment, the development and proving of measuring techniques, and some of the results of measurements. The equipment was first used to measure the characteristics of experimental 1.75-inch-diameter 1,344,000-CM expanded ACSR. Measurements were made later of the characteristics of 1.60-inch-diameter, 1,275,000-CM expanded ACSR, and of 1.75-inch-diameter 1,414,000-CM expanded ACSR. Large quantities of expanded ACSR are being used on the 330-kv systems of the American Gas and Electric Company and the Ohio Valley Electric Corporation.

Equipment

The reactance and a-c resistance of test conductors are calculated from the readings of an a-c potentiometer used to measure the voltage drops along sections of the test conductors, with 60-cps test current flowing. Fig. 1 shows schematically the arrangement of the test conductors, potentiometer equipment, power supply transformer, and current transformer.

The a-c potentiometer comprises a Brooks inductometer, a special voltage divider, and a noninductive volt box. The detector used originally was an a-c galvanometer, with a phase-shifting transformer for the supply of voltage to the field winding. Later an electronic null detector was substituted for the galvanometer and phase shifter, with resulting simplification of operation and increased sensitivity of the potentiometer equip-

The authors acknowledge the valuable contributions of their associates in preparing the paper, particularly the work of J. R. Harvey on the measurement of characteristics of 1.60-inch-diameter expanded ACSR.

ment. Fig. 2 shows the potentiometer equipment.

The volt box is used to provide, for the measuring circuit, a voltage proportional to the voltage drop along the test sections of the specimen conductors. The inductometer provides a voltage proportional to, and in quadrature with, the current in the test conductors. The special voltage divider provides a voltage proportional to, and in phase with, the current in the test conductors.

The a-c potentiometer is balanced by alternate adjustment of the special voltage divider and the inductometer to provide a minimum indication of the null detector. Equations for calculating the values of resistance and reactance of each test sample, from the readings of the potentiometer, are shown in the Appendix. The averages of the individual values for each of the two samples of a pair are taken as the correct values.

Current transformers of high precision are used, and care is taken to maintain the secondary burden on the current transformers at values within their rated burdens. A 60-cps test current is furnished by special, low-voltage high-current transformers which are in turn supplied through multitapped autotransformers. Capacity for test currents up to 10,000 amperes is available. D-c resistances of test conductors are measured with a precision Kelvin double bridge with test current supplied by large storage batteries. A test current of approximately 50 amperes has been used for the measurement of d-c resistance of expanded ACSR.

The calibration of the equipment and the suitability of the measuring technique have been checked by a large number of measurements of reactance and resistance of several sizes of wire and cable of both aluminum and copper. The reactance of such homogeneous conductors, without steel cores, and the ratios of a-c to d-c resistance can be computed with acceptable accuracy. Based on the results of these numerous checks of the equipment calibration, it is believed that most measurements of resistance and reactance are accurate to approximately 1/2 of 1 per cent.

Test Method

In the measurements, two spans of the test conductor are used, each about 120 feet long. The two conductors are taken from a single continuous original length. Each span is subjected to constant tension within the limits of 15 to 25 per cent of the nominal ultimate strength of the conductor. The tension in the two spans is equalized by means of "yokes" and is maintained by a single lever loading system. The conductors are placed parallel to each other with spacings of 1.0 or 2.0 feet and are aligned so that any line perpendicular to both conductors is horizontal. The separation of the two conductors is maintained by means of spacers. After being put into place, the two spans are connected to form a single-phase return circuit. Fig. 3 shows two spans of 1.75-inch-diameter 1,414,000-CM expanded ACSR in position for tests. It also shows the return or cross connection between the two test conductors. The connections to the power supply are made at the opposite ends of the spans. Spans of multilayer test conductors are terminated in compression dead-end bodies. This type of terminal has been proved to insure proper distribution of test current between the strands of the conductors.

Measurements are made of the voltage drop along the central 100-foot sections of the 120-foot test spans. The voltage drop of each of the two conductors is measured in turn. Care was used in the placement of the voltage leads from the test conductors to the a-c potentiometer to minimize possible errors caused by extraneous voltage induced in the leads. The potentiometer equipment is located at some distance from the test conductors in another laboratory room.

Temperatures of Test Conductors

The determination of representative test conductor temperatures has been a problem. Though the laboratory room in which the test conductors have been strung has been kept relatively free of drafts, at times there have been small temperature gradients along the test conductors. Because of this possible gradient, thermocouples have been placed at different points along each test length. At relatively high values of test currents, with appreciable temperature rises, there has appeared to be a definite, though small, temperature gradient, under the test conditions, from the steel core to the outer strands. With 1,400 amperes on the 1.60-inch-diameter 1,275,000-CM expanded ACSR, the steel core temperature has been found to be 3 to 4 degrees Fahrenheit (F) higher than the temperature of the outer layer of aluminum strands. With 2.0-foot spacing between the test conductors and with relatively high values of test current, it has been found that the outer portions of one expanded conductor nearest the other conductor have had slightly higher tempera-

tures than the strands on the opposite side. After considerable experimentation it was decided that the representative temperatures of expanded ACSR could be determined with acceptable accuracy as the average indicated by five thermocouples in each conductor, at 20-foot spacings, at the top of the conductor, between the outer aluminum strands. This arrangement of thermocouples has been used for practically all measurements.

Thirty-gauge copper-constantan thermocouples have been used. Some of the temperature measurements have been made with a precision potentiometer with "cold junctions" in stirred baths of melting ice. Most of the temperature measurements, however, have been made with a portable potentiometer incorporating a cold-junction compensator.

D-c resistances of test conductors have been measured at room temperatures. A-c resistances normally have been measured at increased temperatures caused by the test currents, though not necessarily at equilibrium temperatures. Conductor temperatures have been determined simultaneously with the measurement of reactance and a-c resistance. To determine the ratio between a-c and d-c resistances, the d-c resistance value has been adjusted to the conductor temperature at which the a-c resistance was determined by using the temperature coefficient of resistivity of aluminum. This coefficient has been used for ACSR both because the steel carries very little current and the coefficient of resistivity of steel is approximately the same as that of aluminum.

The values of conductor temperatures obtained during measurements are probably accurate within about 3 F. It is believed that the small variations of calculated ratios of a-c to d-c resistance are largely caused by difficulties in accurately determining conductor temperatures.

Investigation of Possible Causes of Errors

It was questioned whether end effects from current connections at the ends of the spans of test conductors would influence the results of impedance measurements. It had not seemed possible that such errors could be significant with the voltage drop connections arranged as they were. To answer this question, however, measurements were made of resistance and reactance of 100-foot sections of 120-foot spans of 1.75-inch-diameter 1,344,000-CM expanded ACSR. These measurements were then repeated for a central 80-foot section of the same conductors. The test results are included in Table I. The reactance and resistance respectively per mile based on the two sets of measurements were found to be the same. It was therefore concluded that there were no significant end-effect errors in the measurements of the characteristics of the 100-foot sections. All subsequent measurements were made of 100-foot sections of 120-foot spans.

Initial impedance measurements had been made of the characteristics of expanded ACSR with the conductors spaced at 2.0 feet. The spacing, of course, was considerably less than between phases of a practical transmission line. There were questions concerning possible proximity effects at the close spacing. To determine if the proximity effect might be of importance, measurements were made both with 2.0-foot spacing and with 1.0-foot spacing. As shown in Table I, results based on the measurements at the two different spacings did not appear to be significantly different. It was therefore decided that, as there seemed to be no proximity effects discernible in closing the spacing to 1.0 foot, the proximity effect would be entirely negligible at 2.0 feet. Spacings of 2.0 feet were used for all subsequent measurements.

Notes:

1. Measurements made of central 100-foot sections of samples about 120 feet long.
2. Samples strung on 24.0-inch centers.
3. D-c resistances at temperature *T* based on a resistance of 0.0660 ohm per mile at 77 F (25 C).
4. Nominal cross section of aluminum was 1,414,000 CM. Actual cross section was 1,399,000 CM.

The ratios of a-c to d-c resistance, shown in the lower part of Table I, for currents of about 1,200 amperes appear to be slightly lower than found in other measurements. The small discrepancies were thought to be caused by a slightly different and less satisfactory arrangement of thermocouples used for these few check measurements.

In the initial work some discrepancies were noted in the measured reactance of all-aluminum cable with different values of current. It was found that the secondary burden on the current transformers was somewhat too high for most accurate results. Subsequently, much larger secondary leads were installed between the current transformers and the measuring equipment for most of the measurements, and current-transformer ratios were selected to maintain secondary currents between about 4.0 and 5.0 amperes. These steps eliminated the discrepancies.

As may be noted in Tables I, II, III, and IV, there is close agreement between resistance and reactance values determined for each of the two test conductors of each pair. This appears to indicate that the effect of any induced voltages in the voltage drop connections was negligible.

Another Method of Measurement

In addition to the use of a potentiometer for the determination of reactance and resistance of conductors, an attempt has been made to use the wattmeter method, using sensitive galvanometer-type light-beam wattmeters with low-voltage potential windings of relatively high resistance. It was found that this method was less convenient than the potentiometer method, and would be considerably less accurate unless relatively heavy voltage-drop connections were used. With the voltage-drop connections placed for the potentiometer method, as leads to the wattmeter, a voltage drop in the leads caused by the burden of the voltage coil of the wattmeter introduced appreciable error.

Test Results With Experimental 1.75-Inch-Diameter Expanded ACSR

The reactance and a-c resistance of experimental 1.75-inch-diameter 1,344,000-CM expanded ACSR were measured at current values of about 300, 600, and 1,200 amperes. For each current value, impedance values were determined for a range of cable temperatures. Conductor spacing of 2.0 feet was used, with a tension of 7,000 pounds on each conductor. The results are shown in Table II. The reactance at 60 cps for 1.0-foot spacing, based on measured values of 100-foot test sections at 2.0-foot spacings, was found to be 0.332 ohm per mile per conductor. This value appeared to be independent of test current value and conductor temperature, and corresponds to a geometric mean radius of 0.778 inch. The ratio of a-c to d-c resistance was about 1.015. This ratio apparently was substantially independent of the magnitude of current, within the test range, and of conductor temperatures reached. There was some indication that this ratio tends to decrease slightly as conductor temperature increases. This tendency is reasonable, as the skin effect decreases with increasing resistivity caused by increased temperature. The construction of this conductor was similar to that of the 1.60-inch-diameter 1,275,000-CM and the 1.75-inch-diameter 1,414,000-CM expanded ACSR, the details of which are given in Fig. 4.

Test Results With 1.60-Inch-Diameter 1,275,000-CM Expanded ASCR

Measurements were made of the reactance and a-c resistance of this cable at currents of about 900 and 1,200 amperes over ranges of temperature at each current value. In addition, impedance values were determined at 600 amperes at equilibrium temperature. D-c resistance was measured. The measurements were made with a conductor spacing of 2.0 feet, with 7,000 pounds' tension on each conductor.

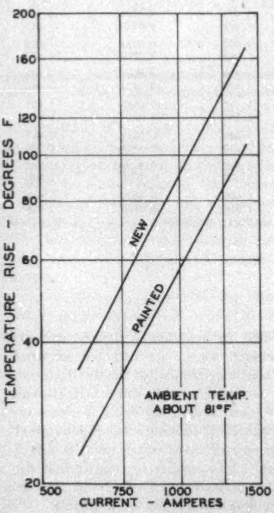

Fig. 5 (left). Temperature rise curves for 1.60-inch-diameter 1,275,000-CM expanded ACSR in free air

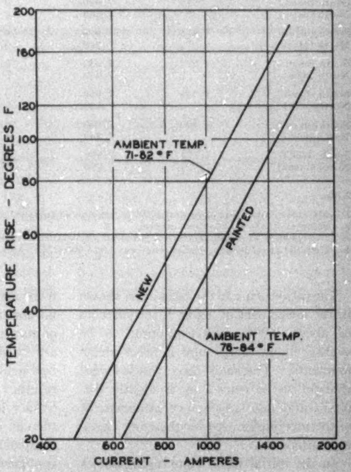
Fig. 6 (right). Temperature rise curves for 1.75-inch-diameter 1,414,000-CM expanded ACSR in free air



Data based on the measurements are shown in Table III.

The calculated reactance per mile, at 60 cps for 1.0-foot spacing, based on measured reactance of the 100-foot test sections at 2.0 spacing, was found to be 0.347 ohm. The ratio of a-c to d-c resistance was found to be about 1.015, and the d-c resistance at 25 C was found to be 0.0717 ohm per mile.

Test Results With 1.75-Inch-Diameter 1,414,000-CM Expanded ACSR

The a-c resistance and reactance of this conductor were determined at currents up to 1,800 amperes, all values being taken at equilibrium temperatures. The measurements were made with a tension of 9,000 pounds per conductor. This represents about $17\frac{1}{2}$ per cent of the designed ultimate strength of the cable.

The data obtained from the electrical measurements are shown in Table IV. As may be seen, the calculated 60-cps reactance for 1.0-foot spacing was found as 0.337 ohm per conductor per mile and is essentially independent of current and temperature. The d-c resistance was 0.0660 ohm per mile at 25 C and the ratio of a-c to d-c resistance approximated 1.015, slightly decreasing, as might be expected, at the higher temperatures.

Discussion

The ratios of a-c to d-c resistances of the three sizes of expanded ACSR may appear low for such large conductors. These low values may be understood by realizing that expanded ACSR is similar electrically to a hollow conductor, in which the skin-effect ratio is relatively low. With even numbers of layers of aluminum strands, losses in the steel core are very low, so that the increase in a-c resistance from this cause is also small.

The geometric mean radii of the three sizes of expanded ACSR, expressed as percentages of nominal radii, are similar (88.9 per cent for the experimental 1.75-inch cable, 86.2 per cent for the 1.60-inch cable, and 85.4 per cent for the 1.75 inch 1,414,000-CM cable).

During the measurements, data were obtained on equilibrium temperature rises of the 1.60-inch-diameter 1,275,000-CM and the 1.75-inch-diameter 1,414,000-CM expanded ACSR. These data were taken with the conductors as they were received from the cable mill, with relatively low emissivity values, and then with the conductors painted flat black, to simulate exteine weathering which could result in relatively high emissivity values. The temperature rise data are shown in Fig. 5 for the 1.60-inch-diameter 1,275,000-CM conductor and in Fig. 6 for the 1.75-inch-diameter 1,414,000-CM conductor. These curves show the temperature rises of the conductor indoors in a relatively draft-free room. Temperature rises with the conductor exposed to natural wind conditions would, of course, be lower.

Following the work on expanded ACSR, work is in progress on a program to obtain complete data on resistance and reactance characteristics of conventional ACSR of the range of sizes available, over wide ranges of current densities.

Conclusions

A convenient and accurate method with suitable equipment is available for the measurement of reactance and a-c resistance of conductors. Such characteristics of a number of sizes of ACSR, including expanded ACSR, have been measured.

Appendix. Calculation of Resistance and Reactance from Laboratory Readings

The a-c potentiometer used in this work is a modification of the customary type in that the standard current is a multiple of the actual cable current. Since the component balance voltages derived from the voltage divider and the inductometer are directly proportional to the current-resistance and current-reactance drops in the cable test length, the divider and inductometer scales may be calibrated directly for R and X. This may be done on the basis of any desired ratio of current transformation and volt box multiplier. In the present case, the instruments are calibrated on the assumption of unity ratio and multiplier. Consequently, the readings must be appropriately modified by the actual ratio and multiplier used.

The cable reactance and a-c resistance are computed as follows

$$X=\frac{G}{N}\frac{(X'+R'\tan\phi)}{\sqrt{(1+\tan^2\phi)}}$$

$$R=\frac{G}{N}\frac{(R'-X'\tan\phi)}{\sqrt{(1+\tan^2\phi)}}$$

where

X = reactance of cable test section, ohms
R = a-c resistance of cable test section, ohms
G = volt box multiplier
N = current transformer ratio
X' = reading of inductometer
R' = reading of voltage divider
ϕ = phase angle of current transformer

When the phase angle is small

$$X=\frac{G}{N}X' \text{ approximately}$$

$$R=\frac{G}{N}R' \text{ approximately}$$

◆

Discussion

C. F. De Sieno (American Gas and Electric Service Corporation, New York, N. Y.): The evaluation of transmission-line losses is playing an increasingly important part in the electric utility industry. This points up the need for accurate conductor data, especially conductor resistance under various loadings and ambient temperatures. This paper therefore is an excellent step towards filling a long-standing gap in the field of electric conductors.

We are particularly thankful to the authors for the work done on the 1.6-inch and the 1.75-inch expanded ACSR because large quantities of these conductors are being used on the 330-kv systems of the American Gas and Electric Company and the Ohio Valley Electric Corporation.

H. B. Dwight (Massachusetts Institute of Technology, Cambridge, Mass.): The measurements on aluminum overhead transmission line conductors given by the authors have evidently been made with great care, and the results are without doubt very valuable.

The reactance of ACSR, except for those cables with a single layer of aluminum wire, can be computed by the geometric-mean-distance method from the dimensions of the conductor. This can be done as a predetermination of the reactance before the conductor is fabricated, and so may be useful for designs and sizes for which tests are not available.

Following the method of Example 5,[1] the 60-cycle reactance of the 1.75-inch conductor of Table IV is 7,920 microhms per 100 feet at 24-inch spacing, to be compared with the measured values of 7,930 to 7,990. For the 1.60-inch conductor of Table III, the computed value is 8,150 microhms per 100 feet, to be compared with 8,160, as measured.

This close agreement as well as other comparisons that have been made justifies the use of the calculations. More reliance should be placed on the calculations. They are not particularly short, but a geometric-mean-distance calculation needs to be made only once for a given design of conductor.

The skin-effect resistance ratio also can be computed, though not with the same precision as the reactance. The steel core does not come appreciably into the computation if the aluminum wires of right-hand and left-hand spiraling are equally balanced so that they do not produce longitudinal magnetization of the core.

If the spacing wires are not considered,

477,000	10+16	2	0.0127	0.430	0.430	0.0

Table VI. Comparison of Test and Calculated Reactance for Expanded ACSR, 60 Cps

Diameter, Inches	Aluminum, CM	Strands of Aluminum	Layers of Aluminum	Test Reactance at 1 Foot, Ohms per Mile	Calculated Reactance at 1 Foot, Ohms per Mile	Difference from Test, Per Cent
1.75	1,344,000	2+2+30+36=70	2 Full 2 Partial	0.332	0.333	+0.3
1.60	1,275,000	2+2+22+28=54	2 Full 2 Partial	0.347	0.346	−0.3
1.75	1,414,000	2+2+26+32=62	2 Full 2 Partial	0.337	0.334	−0.9

the cable may be treated as a stranded tubular conductor. The thickness will be twice the diameter of an outer wire. For the 1.75-inch cable, the ratio t/d is 0.30/1.75=0.172. The resistance of the cable is 0.0660 ohm per mile. Reading at these values from Fig. 8-2,[1] the skin-effect ratio is 1.012.

However, all the aluminum is not within the thickness of 0.30 inch but there are four spacing wires in the region nearer the center, which indicates a higher value of the ratio. If it is assumed that strands are uniformly spread over the thickness of three layers, t becomes 0.30+0.1654=0.4654 and t/d becomes 0.266. Then from Fig. 8-2[1] the ratio is 1.026. This probably can be taken as an upper limit of the ratio, because the four spacing wires are not equivalent to a complete third layer.

By averaging the two values, an estimate of 1.019 is obtained. In a similar manner, an estimate of 1.017 for the skin-effect ratio of the 1.60-inch cable is given. These are in agreement with the measured values, 1.015.

1. ELECTRICAL ELEMENTS OF POWER TRANSMISSION LINES (book), H. B. Dwight. The MacMillan Company, New York, N. Y., 1954, pp. 117–18.

W. A. Lewis (Illinois Institute of Technology, Chicago, Ill.): The authors are to be congratulated on a very clear and straightforward presentation of the test methods and results of tests made to determine the resistance and reactance characteristics of ACSR. Previous tests, including some with which I had been connected at Cornell University, were not made with equipment having the range of currents described in the paper. Therefore, the equipment represents an important extension in the available facilities, and it is gratifying that the results have been made available.

By extending the equations for the reactance of stranded conductors[1-3] to include hollow conductors of the same stranding pattern as the aluminum strands of the conductors tested by Prof. Work, it was possible to make comparisons between test and calculated values of reactance. These equations were based upon the method of geometric mean distances. For all of the conductors tested by Prof. Work, having two or three layers of aluminum strands about a central steel core, it was found that the calculated reactance for the aluminum alone checked very closely the measured values for the complete conductor. The test and calculated values are shown in Table V.

It may be concluded that, for conductors having two or more layers of aluminum strands spiraled in opposite directions about a central steel core, the effect of the steel core on the conductor reactance at spacings of 1 foot and larger, as used in the tests, is completely negligible. The inference to be drawn is that, if the current in the individual strands follows the spiral of the strands to magnetize the core, the spiralling of successive layers in opposite directions permits this effect to be almost completely neutralized.

When samples of the expanded ACSR designs referred to in the paper were being prepared for test, the conductor design data were made available to me and the equations for calculating the reactance were extended to include the effect of the filler layers with only two aluminum strands. The reactances were computed from the design data, neglecting entirely the effects of the steel core (as well as spiraling) but including the effect of stranding by the method of geometric mean distances. The computed results were given to the Aluminum Company of America for comparison with the tested values. Again the agreement was very good, as shown by Table VI.

Because of the excellent agreement in all the comparisons, it may be concluded that the reactance of multilayer ACSR may be calculated with a high degree of precision, based upon the assumptions that the steel core and the spiraling of the strands have a negligible effect and that the current in each strand of aluminum is proportional to its area. This assumption, of course, gives equal currents in all the aluminum strands if the strands all have the same diameter. The final equations have been simplified to permit their ready application.

For ACSR having only a single layer of aluminum surrounding a steel core, reactances calculated using the same assumptions did not agree with test results for completed conductors, as tested by Professor Work. Furthermore, the reactance as well as the resistance, as tested showed variations with current density, starting from a low value at small currents, increasing substantially, and then decreasing again as the current was increased. The low-current value of reactance was only slightly larger than the calculated value, neglecting the core and spiraling effects. It was concluded that the spiraling of a single layer of aluminum about the core caused a substantial effect in the measured reactance and effective resistance that depended upon the flux density in the core and decreased as the core approached saturation.

Because only a limited range of conductors of this type has been given complete tests and because of some inconsistencies among the tests, it has not been possible to prepare tables for the single-layer conductors having the same accuracy as for the multilayer conductors. The plans of the authors to make further tests are therefore very welcome. It is to be hoped that methods of including the core effects in the calculated values, with at least reasonable accuracy, can be perfected so that the resistance and reactance of special conductors such as those of unusually high strength for river crossings can be predicted in advance of actual construction.

A. A. Defoe (Aluminum Laboratories Ltd., Kingston, Ont., Canada): This paper comes at a most appropriate time because during the past few months we have given consideration to the making of similar tests on some of the standard sizes and strandings of ACSR to check presently published values for the a-c resistances and reactances. The method of measurement as described by the authors is direct and fairly simple and from preliminary studies it appears evident that, if sufficient care is taken in the selection of the equipment, installation of test samples, etc., very accurate results should be obtained.

The skin effect and the internal inductance of ACSR are most difficult to calculate with any degree of accuracy owing to the presence of the steel core. This particularly applies to 1- and 3-layer aluminum conductors and especially for the higher current densities. Actual tests are, therefore, a necessity for determining the electrical characteristics of such conductors.

It may be of interest to compare calculated and test values for the a-c to d-c resistance ratio and internal inductance for the 2-layer aluminum 1,414,000-CM 1.75-inch-diameter ACSR mentioned by the authors. The calculated values for the d-c resistance and a-c to d-c resistance ratio are 0.0655 ohm per mile at 25 C and 1.01 respectively. These values compare very favorably with the test results of 0.0660 ohm per mile at 25 C and a resistance ratio of 1.015. For this same conductor, the tests give a reactance of 0.421 ohm per mile with 2-foot spacing. By calculating back, it is found that the external inductance is 1.066 millihenrys per mile and the internal inductance is 0.051 millihenry per mile. By direct calculation, the internal inductance of this conductor is found to be 0.041 millihenry per mile and this is reasonably close to that obtained from the test. However, calculations for the electrical characteristics of other conductors, especially those having one or three aluminum layers, probably would not give values anywhere nearly as close to the test values.

As stated previously, considerable attention should be given to the test setup if the highest possible accuracy in the results is to be obtained. In my opinion, the authors have given this matter the attention it deserves but, for informative purposes, it would be of interest to have their comments on two points which are as follows:

1. In the test setup, compression dead-end bodies are applied to the conductor ends to ensure proper distribution of the current between the strands of the conductors. While it would appear that this procedure is satisfactory for single- or double-layer aluminum conductors, it would seem advisable in the case of 3- and 4-layer aluminum conductors to weld the aluminum wires to the open ends of the aluminum dead-end bodies just to make certain that the current does have the opportunity to distribute itself properly in the conductor.

2. The measurement of the conductor temperature is important, as the authors have stated. From the paper, it is gathered that the thermocouples are placed at the top of the conductor and between the outer aluminum strands. Does this mean that these thermocouples are actually on the outside of the outer aluminum wires or are they between the two layers of aluminum wires?

Joel Tompkins, B. L. Jones, and P. D. Tuttle: We are grateful to the discussers for their remarks concerning the paper and the experimental work behind it.

The comment by Mr. DeSieno concerning transmission line losses is of importance. Prof. Dwight, Dean Lewis, and Mr. Defoe all noted the close agreement between calculated values of electrical characteristics and the results of measurements for ACSR with more than one layer of aluminum strands. Dean Lewis presented data showing that calculated and measured reactance values agree closely for conductors with three, as well as two, complete layers of aluminum strands. We agree, of course, that the reactances and ratios of a-c to d-c resistances can be calculated accurately for ACSR with even numbers of layers of aluminum strands. This fact will reduce considerably the amount of laboratory work necessary to revise published data on the electrical characteristics of ACSR. While it appears that the reactance of ACSR with three layers of aluminum strands can be calculated with acceptable accuracy, measurements of a-c resistance of several sizes of such cables are needed and are to be made. Measurements of reactance will be made simultaneously.

As noted by Dean Lewis, the electrical characteristics of ACSR with single layers of aluminum strands cannot be calculated with acceptable accuracy by neglecting the solenoid effect of the spiraling of the strands. Progress has been made in the development of methods of estimating the characteristics of such cables although it appears that the estimates must be dependent on experimental data concerning the characteristics of the steel cores. Confirming measurements of characteristics of several sizes of ACSR with single layers of strands are needed and are being made.

The simplified equations for the calculation of reactance promised by Dean Lewis will be welcome and helpful. The calculation by the geometric-mean-distance method is laborious for cables with many strands. A simple approximate method has been available for obtaining preliminary data. For expanded ACSR, a computation of reactance based on the equation for a single-phase return circuit composed of tubular conductors, and considering the cable as a tube of outer diameter equal to the cable diameter and of inner diameter equal to the cable diameter less four strand diameters, gave a result differing by less than 2 per cent from the experimental value. The tubular conductor concept also leads to an acceptable estimate of the a-c to d-c resistance ratio, as Prof. Dwight demonstrates.

To answer Mr. Defoe's questions, we have found that compression dead ends, properly applied, seem to meet adequately the requirements of proper current distribution. If there is any doubt, then the cable ends can be welded to be doubly sure, and compression dead ends can be readily adapted to do this. Welding has been used in preparing samples for the measurement of the characteristics of some cables with four full layers of aluminum strands.

We have experimented considerably in regard to the placement of thermocouples to insure satisfactory average readings of cable temperature. We have found no difference in the readings of couples placed between the strands of the outer layer and the couples wedged between the strands of the outer and the first inner layers. The latter position has the advantage of more mechanical security.

Capacitance-Switching Facilities at the Switchgear Development Laboratory

H. N. SCHNEIDER
ASSOCIATE MEMBER AIEE

FACILITIES for capacitance-switching tests to check the performance of circuit breakers when switching the charging currents of transmission lines, cables, or large capacitor banks have been for many years a part of the circuit-breaker development program of the company with which the authors are associated. It had been recognized that severe transient voltages could be encountered when interrupting capacitive currents.[1] In order to develop an interrupter which would minimize these transient voltages[2] a bank of capacitors that provided the means for performing capacitance-switching tests was installed in the High Power Laboratory in Schenectady in 1941. This bank of capacitors had a rating of 7,800 kilovars (kvar) and was arranged for tests up to 132,000 volts. In 1948, an additional 10,800-kvar bank was added, bringing the total capacity to 18,600 kvar. In 1952, when short-circuit testing operations were transferred from Schenectady to Philadelphia[3,4] the 7,800-kvar bank was replaced with a second 10,800-kvar bank, giving a total capacity of 21,600 kvar in the present Laboratory.

With the increase in the number and length of high-voltage transmission lines and cables, and in the use of capacitor banks, the importance of this type of test-

Paper 55-220, recommended by the AIEE Switchgear Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 25, 1954; made available for printing December 17, 1954.

R. L. Williams, L. L. Mankoff, and H. N. Schneider are all with the General Electric Company, Philadelphia, Pa.

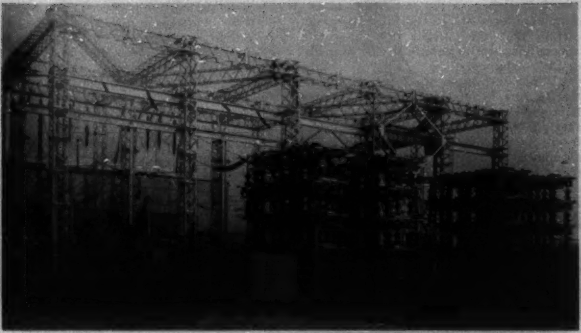

Fig. 1. Capacitor bank and high-voltage yard with 330-kv 25,000,000-kva circuit breaker undergoing capacitance-switching tests

ing has become more generally realized. It is currently being emphasized in the development program to the extent that almost as many capacitance-switching tests are being made as high-power tests.[5]

Because capacitance-switching tests utilized the same power source as interrupting capacity tests, without the actual necessity for such high-power equipment, and since this equipment is in continuous demand for power testing, it has been found advantageous to complement the capacitor bank with new facilities which utilize a synthetic circuit for investigating the capacitance-switching characteristics of developmental interrupters and breakers.

Capacitor Bank Installation

CAPACITOR BANK

Fig. 1 shows the capacitor installation in the foreground with the high-voltage yard in the rear. Power for testing is obtained from one of the two 125,000-kva short-circuit testing generators. One or both of two 100,000-kva 220-kv testing transformers are used to obtain the voltage required for capacitance-switching tests. A 330-kv 25,000-megavolt-ampere breaker is shown undergoing capacitance-switching tests.

The complete installation is built up of 7,200-volt capacitor units with a total of 21,600 kvar on a continuously rated basis. On a short-time basis (10 cycles) the units are capable of withstanding 73-per-cent overvoltages, so that switching tests may be made as high as 64,800 kvar without unduly stressing the capacitors. On this basis the capacitor bank is capable of making tests on a single-pole unit up to the equivalent of 300 miles of 330-kv line. Table I shows the range of capacitance and current available without overexcitation on the capacitors.

Physically, the capacitors are arranged in two identical, 10,800-kvar banks, with space provision for a third bank. Each bank contains 60 trays rated 7,200 volts, 180 kvar. Fig. 2 shows a close-up view of two of the trays, each containing 12 15-kvar capacitor units permanently connected in parallel. Each bank consists of two towers, with 30 trays in 4 tiers per tower. Connections progress from tower to tower and tier to tier in a helical arrangement, Fig. 3, with an insulation level above ground of 750-kv basic impulse level for the bottom tier. The insulation level between tiers is 350-kv basic impulse level. Hook-operated disconnecting switches are provided for making series-parallel combinations of units from 7.2 kv to 432 kv, thus giving a maximum of flexibility in both voltage and capacitance ranges. Fig. 4 shows the operator changing the bank connections by means of these switches.

Two high-voltage lines and two shunt (ground-return) lines for each of the two towers give a high degree of flexibility in making test connections. One high-voltage line of each bank has an insulation level corresponding to the top tier, and the second an insulation level corresponding to the bottom tier. Each high-voltage line has an automatic grounding switch which grounds the line and discharges the bank when the enclosure gate is opened. In addition to grounding switches which discharge the bank as a whole, each capacitor unit has an internal resistor which discharges it down to approximately 50 volts in 5 minutes.

The disconnecting switches for series-parallel connections are mounted on the sides and ends of the tier frames. They are so arranged that no disconnect has the voltage of more than two capacitor units (14.4 kv) so that 23-kv switches may be used. This keeps space requirements to a minimum, and the switches are easily operated from ground level.

In large commercial installations of capacitors, it is customary to equip each capacitor unit with an individual fuse which disconnects this unit from the circuit in case of an internal fault. Experience has shown that, in an installation for laboratory testing, fuses make no contribution to either continuity of service or safety of equipment. Therefore advantage is taken of the simplicity afforded by omitting the fuses. In addition, this simpler connection contributes to minimum inductance in the bank.

Tests are usually made with the test circuit breaker located in the power-test yard; see Fig. 1. Thus, both power tests and line-dropping tests may be made without shifting the location of the test breaker. Where close coupling of the capacitors and a minimum inductance is required, as in bank-to-bank testing, the test breaker is mounted on a test car located on the concrete strip immediately in front of the capacitors. On some occasions special connections within the bank have been made to eliminate even more of the inherent inductance of the bank.

A rod gap is provided to protect the capacitor bank from high transient voltages due to multiple restrikes which occur in the development of new interrupter

units. The rod gap is located on the source side of the breaker with the sparkover voltage adjusted just below the lightning-arrester level. Not only does the gap provide a high degree of protection to the capacitor bank but it also relieves the lightning arrester or surge protector at the transformer terminals of the necessity of discharging the large amounts of energy stored in the capacitor bank.

SYNCHRONOUS TRIPPING OF TEST BREAKER

In order to make a thorough capacitance-switching test on a circuit breaker, the breaker is tested over the complete range of contact-parting angles (the angle on the current wave at which contacts part). This is done to demonstrate that the breaker capacitance-switching ability is adequate for any condition encountered in service. Synchronous tripping is

used to control effectively the contact-parting angle.

Synchronization of the tripping circuit is obtained by means of a control generator which is directly connected to the testing generator. This control generator supplies voltage to a phase-shifting selsyn. The selsyn triggers an electronic circuit that trips the test breaker at any predetermined point on the voltage wave. Fig. 5 shows the control panel used for synchronous control testing.

Recording of Data

Two methods of recording tests, depending upon the use to be made of the data, are employed. If the performance is to be correlated with the breaker travel, speed, pressure, etc., records are made employing both a magnetic oscillograph and the special laboratory-type 3-tube cathode-ray oscillograph producing records on a 6-inch by 40-inch film having a wide selection in time scale. Figs. 6 and 7 show typical oscillograms for such a test.

Most capacitance-switching tests do not require the elaborate oscillograms referred to in the foregoing paragraph. For these tests, all essential data are obtained by using a 4-beam cathode-ray oscillograph, having a long-persistence screen, from which a still photograph is made of the transient phenomena with a 35-millimeter camera. With this method of recording, tests are made at approximately three times the former rate, effectively tripling the availability of the test facilities for capacitance-switching tests. Fig. 8 shows a 35-millimeter record of two capacitance-switching tests, one with restrike and one without restrike.

Synthetic Circuit for Capacitance Switching

Basic Circuit

The Development Laboratory has the forementioned capacitance bank installation in the high-voltage yard to provide means of determining full-scale capacitance-switching performance of breakers. These tests are made to demonstrate that the breaker being tested can successfully handle, with adequate margin, capacitance switching. However, in the development of new interrupters it is not sufficient merely to determine successful performance for a given voltage. To evaluate adequately capacitance-switching characteristics of developmental interrupters, it is necessary to investigate the factors that contribute to performance such as interrupter configuration, contact design, contact speed, etc.

In addition to this, it has been found that for a given set of conditions there is no sharp boundary between the region where no restrikes occur and the region where restrikes occur all of the time. On the contrary, the voltage at which restrikes occur all of the time may be as much as two to three times greater than the voltage at which no restrikes occur. Also, this investigation should be made over the whole range of contact-parting angles because changes in the contact-parting angle can result in more than 100-per-cent variation of withstand voltage, and this variation changes with interrupter modifications. Since this investigation must also be made over a wide range of currents, it is apparent that, to evaluate a single modification of a developmental interrupter, many hundreds of tests must be made.

The conventional method of performing capacitance-switching tests requires the high-power facilities and large test areas of the Switchgear Development Laboratory which are in continuous demand for power testing. However, capacitance-switching tests require only a small fraction of this available power. Recognition of this fact led to the development of a synthetic circuit which is used for evaluating the capacitance-switching performance of developmental interrupters and circuit breakers. This synthetic circuit utilizes relatively low power equipment and a small test area. In essence the circuit supplies capacitive current from a low-voltage source and high test voltage from a low-current source. Synchronous isolation of the two power supplies is provided by means of a device designed for this purpose.

Synthetic circuits for investigating developmental interrupters and circuit breakers have been under consideration many times. Synthetic circuits for power testing require the application of a high-frequency, recovery voltage accurately controlled within a few microseconds of the current zero. Fortunately this is not the case for capacitance-switching testing. The recovery voltage is a 60-cycle wave and application within 100 microseconds will suffice.

Fig. 9 shows the basic circuit and wave forms of the synthetic test unit. The high-potential transformer is energized with the contacts of the interrupter closed; therefore, the high potential is impressed across the series capacitor whose 60-cycle reactance is high enough so that it will not overload the high potential transformer. To insure steady-state conditions, a minimum of 10 cycles, set by a time-delay unit, are allowed before any

action is initiated by a synchronous-control unit. As can be seen from the waveforms the current generator is preset to fire so that current zero will occur at a voltage maximum. The current generator is fired synchronously and current begins to flow through the closed contacts. The current generator produces a half-cycle of current. At the desired time within the half-cycle the contacts part and the current continues to flow in an arc produced across the parting contacts. This arc maintains a low-impedance path for the high potential. At the end of the half-cycle of current the isolating device has removed the current generator from the circuit. The high-potential transformer voltage is then at a positive peak, and the series capacitor is charged to a voltage E_{max}. Voltage now builds up across the interrupter contacts and reaches $2E_{max}$ after 1/2 cycle.

The current generator is a bank of capacitors charged from a rectified a-c source and synchronously discharged through an inductance by means of a thyratron-trip circuit. The amount of capacitance used is governed by the range of current desired and the inductance is chosen to resonate with the capacitance at 60 cycles per second. Fine control of the amount of current obtained is achieved by adjusting the alternating voltage applied to the charging circuit.

Both the current and the voltage are displayed on a cathode-ray oscillograph. The current is measured by means of a shunt, the voltage by means of a capacitance divider across the interrupter or breaker. The contact-opening indication is obtained through the use of a switch set to fire a thyratron which in turn blanks the trace for a short interval at the time of contact opening. The composite signal, on a single trace, is obtained from a signal-mixer unit which amplifies and combines the current and voltage signal. Fig. 10 is a typical oscillogram showing current, contact indication, and voltage. The first half-cycle shown is the current wave. The remainder of the oscillogram is the voltage applied to the interrupter. In recording, the polarity of the voltage wave is reversed. This is done to position the voltage wave on the oscillograph in order to improve the readability of the test record. When it is required to record additional test data such as contact travel, interrupter pressure, etc., a 4-beam cathode-ray oscillograph is used.

The device developed to provide synchronous isolation of the two power supplies was tested extensively. In addition, to insure the reliability of the data obtained, the proper operation of this device is checked on each test. This is accomplished by means of an indicating circuit which is actuated in the event of a rare isolation failure. This circuit will blank the cathode-ray oscilloscope beam at the instant of failure, thereby recording that the test was not valid. It is to be noted that this synthetic circuit cannot be applied to interrupters that are shunted by resistors of such ohmic value that would effectively discharge the series capacitor of the synthetic circuit.

Synthetic-Circuit Installation

A permanent installation of this synthetic capacitance-switching circuit has been made in the Development Laboratory as shown in Fig. 11. This installation is divided into a control area, which is located in the upper left corner of photograph below the clock, a circuit area, which is located at rear of photograph, and two test areas, in the foreground. The circuit area contains the following components:

Fig. 11. Installation of synthetic capacitance-switching circuit. Directly in the foreground are the two test areas. Behind the test areas is the circuit area that contains the synthetic circuit. To the left of the circuit area, and underneath the clock, is the control area

Fig. 12. Control area of synthetic capacitance-switching circuit showing, from left to right, the incoming power panel, synchronous control unit no. 1 instrument panel and calibration unit, and synchronous control unit no. 2. To the extreme right is seen the cathode-ray oscillograph and 35-millimeter camera

1. Voltage regulator.
2. High-voltage transformer.
3. Series capacitor.
4. Capacitance voltage divider.
5. Isolation device.
6. Current generator.

The two test areas are interlocked so that testing can be done in one area while another test unit is being prepared in the other. The interlock circuits are controlled by the position of the single-pole double-throw high-voltage switch mounted above the rear fence of the cell areas, as shown in Fig. 11. The test-unit control wiring plugs into stationary receptacles which connect to the synchronous-control unit associated with each test area. Jumper connections in the circuit area provide for the interchanging of the synchronous-control units. The front fencing of the two test areas is removable to allow test breakers, as well as test units, to be brought into the test areas.

The control area, as illustrated in Fig. 12, incorporates the following components:

1. Incoming-power control panel.
2. Instrument panel that transmits the test data to the cathode-ray oscillograph. Data is recorded on a 35-millimeter camera mounted on the oscillograph.
3. Calibration unit.
4. Two electronic synchronous-control units which are used to synchronize the current, voltage, isolation device, test-breaker operation, and oscillograph sweep.

PHOTOGRAPHIC STUDY OF CAPACITANCE SWITCHING

In addition to capacitance-switching testing, this installation, with the synchronous-control units, has provided the means necessary to pursue a photographic study of the fundamentals of capacitance-switching phenomena. Using both still and high-speed motion photography, arcs, of the magnitude and duration encountered in capacitance-switching duty, are being investigated. The effects of transient fluid flow, contact motion, interrupter geometry, etc., are being studied. Restrike action at voltage breakdown is being observed. The contributions to understanding being obtained from this study demonstrate another benefit of this new facility.

Conclusions

The capacitance-switching facilities of the Switchgear Development Laboratory have been expanded in step with capacitance-switching performance requirements. The capacitor bank installation has been increased in capacity and new testing procedures have multiplied the utility of the testing facilities.

A synthetic circuit for capacitance switching has been installed and has proved to be a very useful tool. It has been applied to investigating many types of developmental interrupters and breakers. To date over 15,000 tests have been performed on oil-blast, air-blast, and magne-blast developmental interrupters.

The main value of the synthetic circuit is as a developmental tool. It is important to recognize that verification tests of the capacitance-switching performance of the final design of interrupter or breaker must be determined through the use of full-scale tests using equipment such as capacitor bank and high-power facilities available at the Switchgear Development Laboratory.

Discussion

A. E. Kilgour (Allis-Chalmers Manufacturing Company, Boston, Mass.): The authors are to be congratulated for this paper, which they have so well prepared and presented. Throughout the text there is no mention of measuring the voltage drop across the circuit-breaker contacts. It is this initial drop as the capacitors are removed from the circuit that will affect the history of breaker interruption. Important with respect to the synthetic testing at this same stage of interruption is the ratio of the kvar kva short circuit. Such has not been mentioned within the paper.

A second question follows from paragraph 5 of the section on "Basic Circuit." The second sentence beginning "The high-potential transformer voltage..." This statement seems to be in conflict with information presented in two other papers.[1,2] The conflict that arises concerns the voltage at which the breaker should be tested.

R. L. Williams, L. L. Mankoff, and H. N. Schneider: The voltage across the circuit-breaker contacts is available both in full-scale and synthetic circuit capacitance switching testing. In capacitance switching testing, using full-scale testing facilities, the voltage is measured on each side of the breaker to ground. The difference of the voltages is the voltage across the breaker contacts. Any initial voltage drop across the breaker contacts will appear on the voltage trace of the source side since the voltage of the load side will remain constant. For the synthetic test circuit as stated in the paper, voltage is measured directly across the breaker contacts. It is a property of the synthetic circuit that the initial change in voltage across the breaker contacts upon interruption is zero, corresponding to the most severe test condition with regard to kvar to kva short-circuit ratio.

There is no conflict between this paper and the two mentioned by Mr. Kilgour. They establish the voltages that should be used for the single-phase circuits equivalent to the various 3-phase conditions. The $E_{\max}$ of the present paper designates the crest value of the transformer voltage of the synthetic circuit, which may be set at the same value as that required for the single-phase equivalent circuit or for any other voltage desired. In fact, for developmental investigations, testing is done through a range of voltages far in excess of any encountered under field conditions.

Stray Losses in the Armature End Iron of Large Turbine Generators

R. L. WINCHESTER
ASSOCIATE MEMBER AIEE

Synopsis: The results of a study of stray load losses in the armature end iron of large turbine generators are presented. These losses are induced by the generator end leakage flux, and the resulting end iron temperatures limit the machine capability in the underexcited region of operation. Quantitative methods of analysis of the magnetic field distribution at the ends of the machine and the resulting losses and temperature rise are presented. Design innovations for reducing end iron losses and temperature in both conventional and direct-cooled generators are described. The results of factory and field tests supporting the principal conclusions are included.

IT WAS recognized early in the history of synchronous machines that generator operation at high lagging, unity, and leading power factors resulted in comparatively high temperatures in the structural parts at the ends of the armature core. This phenomenon has been termed "end heating" and is characteristic of the steam turbine type of alternator.

End heating is caused by losses generated in the structural parts by magnetic flux entering the ends of the armature core. This flux is caused by the resultant of the armature and field winding magnetomotive forces (mmf) and rotates in synchronism with the field. The parts affected, shown in Fig. 1, are the end laminations of the stator core, the stator core clamping fingers, the stator core flanges, and the end winding binding bands.

During the early years of electric power generation, little capacitive correction was used on transmission systems. Under these conditions, the generator supplied most of the reactive power. Most early units carried loads ranging from 0.7 to 0.9 power factor, overexcited, and performed satisfactorily with such loads. In later years, with the application of static capacitors and synchronous condensers, system power factors, during light load periods especially, have gradually shifted closer to unity.

In about 1925, the General Electric Company made turbine-generator design alterations which materially reduced the high temperatures resulting from underexcited operation. These changes consisted of using nonmagnetic steel for the structural parts, fingers, flange, and binding bands, which were previously made from magnetic steel. Additional improvement was made later by introducing the practice of chamfering the end packages of the stator core.

The reduction in temperature rise obtained by these improvements, documented by test results on many machines through years,[1] has promoted increased confidence on the parts of both the manufacturer and the operator in the underexcited capability of modern turbine generators. All turbine generators currently being built by the General Electric Company are capable of operating at rated kilovolt-amperes (kva) at 0.95 power factor, underexcited, and may be loaded to approximately 60 per cent of rated load at zero power factor, underexcited. A typical operating characteristic for one of these machines is shown in Fig. 2.

During the past few years, rather intensive, industry-wide efforts by turbine-generator designers have been devoted to increasing the specific capacity of 2-pole generators. Hampered on one hand by limits of shipping weight and dimensions and on the other hand by the mechanical limits of known structural materials, the designer has had to devise radical improvements in methods of cooling to increase the kva capacity of 2-pole turbine generators. Significant progress has been made in the design of direct-cooled generators[2-6] and in the design of multiple-circuit generators and multiple-phase generators[6] which also allow an appreciable increase in generator capacity.

The greatly increased specific capacity of these direct-cooled machines has resulted in greatly increased loadings on the generator windings. It is to be expected that the losses at the ends of the armature core will increase correspondingly. An idea of the increase in end iron temperature to be expected by simply increasing the winding loading of a large 2 pole generator may be gained by inspection of Fig. 6 of reference 1. This curve shows that a 10-per-cent increase in capability for a given generator will cause an increase in the end iron temperature of approximately 13 per cent if no other design changes are made. What, then, is to be expected if the generator rating is increased 50 per cent or even 100 per cent or more without an increase in physical size?

The results of a study directed towards gaining a better understanding of the nature of end iron losses are described.

Paper 55-130, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing December 8, 1954.

R. L. WINCHESTER is with the General Electric Company, Schenectady, N. Y.

The co-operation of the Pacific Gas and Electric Company in carrying out tests described in this paper is gratefully acknowledged. The author also wishes to acknowledge the encouragement of B. M. Cain and C. H. Holley, and the help of H. Poritsky and S. J. Jennings whose initial work on this problem eliminated many roadblocks. Finally, C. B. Linkous, H. Kitson, and T. F. Salmon made direct contributions while on rotating engineering assignments from the General Electric Advanced Engineering Program.

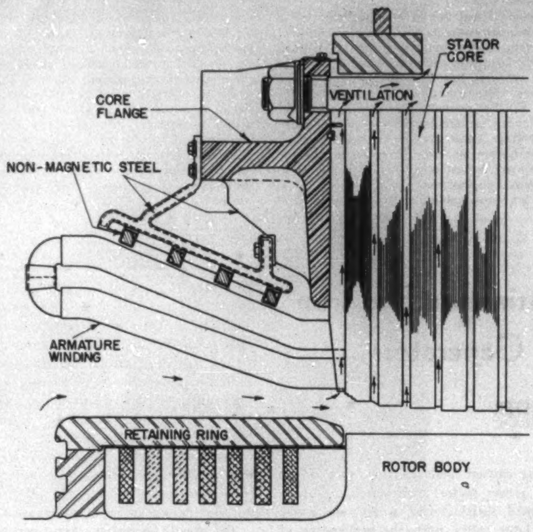

Fig. 1. Typical turbine generator end construction

This study was undertaken with the intent of learning how to design generators of increased capability with end iron temperatures consistent with those of conventional units over the entire range of operating conditions. In addition, the end losses, which appear as stray load losses become of an appreciable magnitude in up-rated generators and methods have been devised to reduce these losses. The progress which has been made towards the predetermination of end iron losses and temperature, and the loss reduction features which will be introduced in large direct cooled-generators currently being built by the General Electric Company are presented. This problem, the initial results of which are described in this paper, is just one of many similar problems inherent to the large direct-cooled generator. These problems have required, and will continue to require, thorough engineering study in advance of construction and operation to assure satisfactory and lasting operation.

Nomenclature

A_{sw} = square wave armature reaction
$\mathbf{B}$ = magnetic induction
$\mathbf{E}$ = electric field intensity
f = frequency
$\mathfrak{F}$ = magnetomotive force
$\mathbf{H}$ = magnetic field intensity
$\mathbf{J}$ = electric current density
k_p = armature winding pitch factor
k_d = armature winding distribution factor
P = number of poles
r = radius from generator centerline
V = scalar magnetic potential
x,y,z = rectangular co-ordinates
δ = depth of penetration
θ = generator peripheral angle
ρ = electrical resistivity
ρ_c = resistivity of copper
ω = angular frequency
μ = magnetic permeability
μ_0 = permeability of free space

Description of the Nature of End Iron Losses

The purpose of this section will be to discuss, from a qualitative standpoint, the nature of the losses which occur in the structural parts at the ends of the armature core. The emphasis will be placed on establishing a physical picture of the magnetic field distribution at the ends of the machine, the behavior of the conducting materials in the presence of this field, and the effect of load conditions on losses and temperature rise.

End Construction

The end construction of a typical turbine generator is shown in Fig. 1. Axial pressure is maintained on the stator core laminations by the stator core flange, which is bolted in place on extended key bars in back of the stator core. Beneath the stator core flange against the core are located the outside space blocks, or end clamping fingers, which extend as cantilevers over the core teeth between armature bar slots and maintain axial pressure on the core teeth. The armature end windings extend axially from the slots and are laced to binding bands in the usual diamond-shaped pattern. The field end windings extend axially from the rotor body and are held in place by the retaining ring. The retaining ring is shrunk onto the rotor spindle and a small air gap is maintained between the tip of the retaining ring and the rotor body.

Magnetic Field Distribution

Under normal load conditions, the generator voltage is produced by magnetic flux which passes radially across the air gap and is distributed uniformly over the length of the core and approximately sinusoidally with the peripheral angle. This air-gap flux rotates in synchronism with the field and is generated by the resultant of the armature and field winding mmf.

The end losses are generated by the end fringing flux which passes from the ends of the rotor body and retaining rings to the ends of the armature core. This flux is produced by the winding mmf, just as is the main air-gap flux, the difference being that the permanence paths are in general longer and more complicated. The end flux rotates in synchronism with the field and, therefore, sweeps past the stationary parts at the ends of the armature core at synchronous speed, inducing eddy-current losses.

Skin Effect in Conducting Materials

The losses in the various structural parts may be separated into two categories. In the first case, the eddy currents are resistance-limited, or the effective resistance to eddy-current flow is considerably larger than the effective reactance, i.e., there is little skin effect. In this case, the distribution of the magnetic field is relatively unaffected by the presence of the conducting material, and the eddy-current distribution is determined largely by the properties of the material and the magnetic field distribution.

In the second case, that of pronounced skin effect, the eddy currents are reactance-limited. In this case, the conducting material has a dominating effect on the magnetic field in its vicinity, the eddy currents being large enough to prevent the entry of magnetic flux and tending to cause the conductor to act as a shield.

The criterion to be applied to determine to which category the materials belong is the classical depth of penetration of the material. The magnetic field attenuates within a conductor (the proportions of which are large in comparison to the depth of penetration) to a value, at a point one depth of penetration below the surface, of 37 per cent of the value at the surface. The classical depth of penetration is defined as

$$\delta = \sqrt{\frac{2\rho}{\omega\mu}} \tag{1A}$$

$$= \frac{0.336}{\sqrt{\left(\frac{f}{60}\right)\left(\frac{\mu}{\mu_0}\right)\left(\frac{\rho_c}{\rho}\right)}} \text{ inch} \tag{1B}$$

The case of pronounced skin effect occurs when the dimensions of the conducting body are large in comparison with the depth of penetration, while little skin effect occurs when the dimensions are small in comparison with the depth of penetration.

EDDY-CURRENT LOSSES IN STRUCTURAL PARTS

Magnetic flux entering the end teeth of the stator core in an axial direction induces eddy currents which flow unobstructed parallel to the laminations. It has been demonstrated that a given magnetic induction entering a laminated steel body in a direction perpendicular to the laminations generates losses many times greater than the same induction entering parallel to the laminations. Eddy currents in the end teeth are largely resistance-limited except in generators with the widest teeth. The primary reason for this behavior is that the effective permeability of the stator core to axial penetration of magnetic flux is quite low because of the air gaps between laminations.

As was described previously, the binding bands, binding-band brackets and outside space blocks of the machines currently being built by the General Electric Company are made from nonmagnetic steel. The eddy currents in these parts are resistance-limited since the dimensions are small in comparison with the depth of penetration. The losses in these parts are minimized by the nonmagnetic steel construction.

On the other hand, the dimensions of the stator core flange are such that with presently used materials the currents are nearly reactance-limited. Therefore, the core flange eddy currents prevent most of the end flux from penetrating the flange and from entering the backiron. The current flowing in the flange is a small fraction of the total end winding current, the actual magnitude depending on the geometry of the end structure. Magnetic steel and cast-iron flanges behave in a similar manner except for more pronounced skin effect and higher losses than with the nonmagnetic steel construction.

With the generator operating at rated load and rated power factor, the end losses and resulting end iron temperatures are well within comfortable limits. The losses and temperature rise increase rapidly, however, as the generator loading is shifted into the underexcited region of operation[1] and, finally, actually limit the generator capability, as shown in Fig. 2. This increase in end losses and temperature is caused primarily by the changes in the magnitude and relative spatial positions of the winding mmf. As the generator loading is shifted towards underexcited operation, the locations of the peak values of the armature and field winding mmf move towards one another, and the field winding mmf decreases in magnitude. Both of these effects cause an increase in the end leakage flux and the resulting losses.

EFFECT OF NONMAGNETIC RETAINING RINGS

End losses are, in general, lowered by providing nonmagnetic retaining rings on the rotor. The presence of a nonmagnetic retaining ring tends to increase the lengths of the reluctance paths for the end leakage flux, lowering the magnetic field intensities and decreasing the losses.

Although nonmagnetic retaining rings are ideal from an electrical standpoint, there are many problems of quality control in producing these rings for large generators. As a consequence, engineering effort has been directed towards developing loss reduction features applicable to direct-cooled generators with magnetic retaining rings as well as towards solving the problems of manufacture of nonmagnetic retaining rings.

Results and Conclusions

End iron temperature rise margins in generators of conventional rating have been greatly increased by the introduction of split teeth in the end laminations of the

stator core. The striking effect of split end teeth on end tooth temperature rise has been demonstrated by generator field tests and is illustrated in Fig. 3 which shows a comparison of temperature rise in duplicate machines, except for solid and split end teeth.

Slotting the end teeth accomplishes, to a lesser degree of perfection, the same effect as laminating the core in a direction parallel to the magnetic flux. This loss reduction technique was first described, as far as the author is aware, with reference to the generator end loss problem, in the foreign literature.[7]

It is expected that direct-cooled generators with greatly increased specific capacities, currently being built by the General Electric Company, will have capabilities in the underexcited region of operation similar to those of conventional units. This operation has been made possible by the development of design innovations consisting of split teeth in the end laminations of the stator core and a conducting shield over the stator core flange. The introduction of these design features will also help to maintain high efficiency in direct-cooled generators.

The stator core flange shield consists of a copper shield bolted in place over the stator frame flange. This device allows the currents which otherwise flow in the flange to flow in the low-resistance shield, reducing the losses. Factory tests have been run with temporary shields of this type and are described later.

Progress has been made towards a complete understanding of the stray losses at the ends of the armature core in large turbine generators. It is hoped that the results will stimulate further investigation of this problem, and lead ultimately to a thorough understanding of the over-all generator stray load loss.

Outline of Analytical Methods and Substantiating Test Data

The analysis of end iron losses and temperature rise in large turbine generators has involved a fundamental study of the magnetic field distribution at the ends of the machine, an investigation of the flux distribution and eddy-current losses in the end teeth and fingers, and a study of the thermal characteristics of the ends of the core. The analytical methods will be outlined and the results of calculations will be compared with test data gathered on models and during generator factory and field tests.

MAGNETIC FIELD DISTRIBUTION

The magnetic field at the ends of the armature core forms a fairly complicated 3-dimensional configuration. A solution to the problem has been obtained using an electrolytic field-mapping tank especially equipped to account for the various features of the problem.

Electrolytic Tank Analogue

It is well known that 2-dimensional as well as axially symmetric Laplacian field problems may be solved by analogue methods. Among the techniques available are hand flux plotting, resistance paper, electrolytic tank, d-c calculating board, and digital computer studies. In this case the electrolytic tank seemed to be the most adaptable to the problem.

In the electrolytic tank analogue, electric voltage in the tank is analogous to the mmf in the machine, and the electric current is analogous to magnetic flux. The geometry of the generator end structure is axially symmetric, requiring a wedge-shaped tank in which the electrolyte depth varies with the radius from the generator axis of rotation.

Since the generator winding mmf vary sinusoidally with the peripheral angle, considering only the fundamental component, peripheral flux exists within the end region and should be accounted for in the analogue solution. A technique has been developed which allows the representation of the peripheral as well as the axial-radial fields in a wedge-shaped tank.

The magnetic field in the air regions at the ends of the machine may be obtained as the gradient of a scalar potential, where the potential must be a solution of Laplace's equation. Laplace's equation, in cylindrical co-ordinates, is

$$\nabla^2 V = \frac{\partial^2 V}{\partial r^2} + \frac{1}{r}\frac{\partial V}{\partial r} + \frac{1}{r^2}\frac{\partial^2 V}{\partial \theta^2} + \frac{\partial^2 V}{\partial z^2} = 0 \qquad (2)$$

where

$$\mathbf{H} = -\nabla V$$

Since the winding mmf are distributed sinusoidally with the peripheral angle, the potential V will also be sinusoidally distributed.

Let this potential be written as

$$V = V'(r,z)\cos\frac{P\theta}{2} \qquad (3)$$

Then the potential equation 2 in terms of the new potential V' is

$$\frac{\partial^2 V'}{\partial r^2} + \frac{1}{r}\frac{\partial V'}{\partial r} + \frac{\partial^2 V'}{\partial z^2} = \left(\frac{P}{2}\right)^2 \frac{V'}{r^2} \qquad (4)$$

Thus the distribution of the potential in any radial plane is independent of variations with the peripheral angle.

Equation 4 is Laplace's equation for an axially symmetric field except for the presence of the source term on the right-hand side. It may be shown that the potential distribution may be determined by any of the analogue methods applicable to axially symmetric fields providing suitable sources are located throughout the plane of the solution. In the electrolytic tank, probes were located throughout the plane of the tank and grounded through suitable resistances. The current absorbed by these probes corresponds to magnetic flux leaving the corresponding radial plane in the generator to travel in a peripheral direction. The actual field-mapping tank and pantograph plotting equipment is shown in Fig. 4.

Winding Mmf

The winding mmf are obtained by evaluating the equivalent axial and peripheral currents in the end windings. The mmf were represented in the electrolytic tank by voltage sources located on the radial centerlines of the end windings. The strengths of the voltage sources are a maximum at the ends of the core and decrease, depending on the end winding geometry, with axial distance from the core to zero outside the windings.

Magnetic Retaining Rings

Magnetic retaining rings were represented by additional current sources. Magnetic retaining rings in large turbine generators are saturated, except at very low field currents, by the large field mmf. The saturated rings may, therefore, be represented by current sources which simulate the intrinsic ring saturation level. The strengths of these sources depend only on the retaining ring material and geometry and are independent of load conditions.

Boundary Conditions

The boundaries, end teeth, rotor body, stator frame, and end shields, were represented as infinitely permeable materials. It will be shown that skin effect is of second order importance in the end teeth, hence these may be represented, as far as the magnetic field distribution in the air region is concerned, as infinitely permeable surfaces. The end shields and stator frame, generally made from magnetic steel, can only be approximated by infinitely permeable surfaces because of pronounced skin effect. Since these surfaces are relatively distant from the regions of primary interest, the approximation is of sufficient accuracy. Boundary conditions for the stator core flange will be discussed later.

The end result of the field mapping study is the determination of the magnetic field intensities in the various regions of interest for varying load conditions. Proper account must be made of the phase displacement of armature and field winding mmf in evaluating the magnetic field intensities under load conditions. The evaluation of eddy-current loss from known field intensities is described in the following.

Loss in End Teeth and Fingers

End leakage flux entering the end teeth normal to the laminations induces eddy currents, and the resulting loss is many times greater than for the same magnetic induction entering parallel to the laminations. The magnitude of the losses depends on the normal induction, determined from the field study, and the distribution of flux within the end teeth.

Axial Penetration of End Flux

It will be shown that skin effect is relatively unimportant in determining the tooth flux distribution except in generators with the widest teeth. Under this condition, the degree of axial penetration of the end flux into the core is determined by the magnetic circuit of the end packages of the stator core.

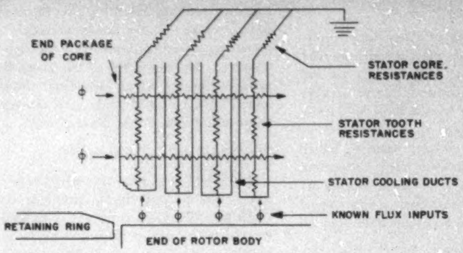
An equivalent circuit representing the end packages of the core is shown in Fig. 5. The magnetic reluctances of this network are determined from the dimensions and permeability of the core material, and the flux inputs are evaluated for the particular load condition being studied. The network can be made as detailed as necessary to obtain a reasonable approximation to the axial flux distribution. The network solution must account for the nonlinearity of the core material.

Solution of equivalent circuits of the type shown in Fig. 5 indicates that the end flux is confined largely to the first package of laminations in modern generators of conventional rating. The axial flux in the end package decreases nearly linearly with depth into the package, except for variations just below the end surface.

Tooth Loss Intensity

The tooth loss intensity and the distribution of the axial field over the width of an end tooth may be evaluated by an analysis from fundamental field theory. The geometrical configuration is shown in Fig. 6. The object here is to evaluate the tooth eddy-current loss intensity in terms of known axial fields at the end surface.

Fig. 4. Three-dimensional field-mapping tank and associated equipment



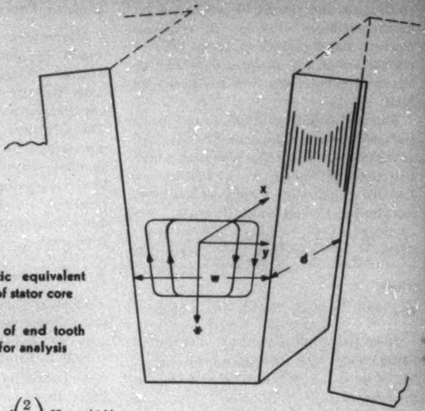


Fig. 5 (above). Magnetic equivalent circuit for end packages of stator core

Fig. 6 (right). Geometry of end tooth and co-ordinate system for analysis

It will be assumed that the end flux spanning one tooth and slot pitch enters the tooth end face uniformly over the tooth width, and that the eddy currents are 1-dimensional. The first assumption is based on the fact that the iron permeability is considerably larger than that of the air paths. The second is an approximation, but is justified on the basis that the tooth depth is considerably larger than the tooth width, and the rate of change of the axial field with the radial tooth dimension is small except over a short distance near the tooth tip. The problem will be solved first on the basis that the axial field is continuous, and then modified to account for the fact that the axial field intensity decreases with depth into the package.

Maxwell's field equations, on neglecting variations in the z direction and replacing $\partial/\partial t$ by $j\omega$ for steady conditions, are

$$\frac{\partial H_y}{\partial x}-\frac{\partial H_x}{\partial y}=J_z \qquad (5A)$$

$$\frac{\partial E_z}{\partial y}=-j\omega B_x \qquad (5B)$$

$$\frac{\partial E_z}{\partial_x}=j\omega B_y \qquad (5C)$$

Ohm's law is written as

$$\mathbf{J}=\frac{\mathbf{E}}{\rho} \qquad (5D)$$

and

$$B_x=\mu_x H_x \qquad (5E)$$

$$B_y=\mu_y H_y \qquad (5F)$$

In writing equations 5(E) and 5(F), cognizance is taken of the fact that the core permeability in a direction perpendicular to the laminations is considerably less than when parallel to the laminations because of the air gaps between laminations. Constant permeability parallel to the laminations is assumed. Differential equations for the magnetic field intensities may be derived from equations 5 in the following form

$$\frac{1}{\alpha}\frac{\partial^2 H_x}{\partial x^2}+\frac{\partial^2 H_x}{\partial y^2}=\frac{j\omega\mu_x}{\rho}H_x=j\left(\frac{2}{\delta^2}\right)H_x \qquad (6A)$$

$$\frac{1}{\alpha}\frac{\partial^2 H_y}{\partial x^2}+\frac{\partial^2 H_y}{\partial y^2}=\frac{j\omega\mu_x}{\rho}H_y=j\left(\frac{2}{\delta^2}\right)H_y \qquad (6B)$$

where

$$\alpha\equiv\frac{\mu_y}{\mu_x}$$

$$\delta\equiv\sqrt{\frac{2\rho}{\omega\mu_x}}$$

The solution of equation 6, subject to the boundary conditions of a uniform field H_0 at the face of the tooth and all the flux to be carried in the iron, is

$$H_x=H_0\left[\frac{(1+j)w}{2\delta}\,\frac{\cosh\,(1+j)\,\dfrac{y}{\delta}}{\sinh\,(1+j)\,\dfrac{w}{2\delta}}-\sum_{n=1,2,3}^{\infty}\left(\frac{4j}{\gamma^2}\right)\cos n\pi\cos\frac{2\pi ny}{w}\,\epsilon^{-\beta x}\right] \qquad (7)$$

where

$$\beta^2\equiv\alpha\left[\left(\frac{2\pi n}{w}\right)^2+j\,\frac{2}{\delta^2}\right]$$

$$\gamma^2\equiv\left(\frac{2\pi n\delta}{w}\right)^2+j2$$

The first term of equation 7 is the field distribution at some distance into the tooth, while the second term accounts for the redistribution which occurs just beneath the surface. This solution describes the behavior to be expected, i.e., the magnetic flux tends to crowd to the outside surfaces of the tooth.

The power loss intensity may be obtained as the real part of

$$P=\frac{1}{2}(j\omega\Phi)i \qquad (8)$$

where

$$\Phi=w\mu_0 H_0=wB_0$$

$$i=\int_{x=0}^{d}H_x\Big|_{y=\frac{w}{2}}dx$$

and peak values of the time-varying quantities are used. The result of evaluation 8 is

$$P=\frac{\omega^2 B_0^2 w^3 d}{24\rho}\left[\left(\frac{3\delta}{w}\right)\left(\frac{\sinh\dfrac{w}{\delta}-\sin\dfrac{w}{\delta}}{\cosh\dfrac{w}{\delta}-\cos\dfrac{w}{\delta}}\right)-\frac{24\delta^3}{\alpha^{1/2}w^3 d}\sum_{n=1,2,3}^{\infty}\frac{\gamma_r\alpha_r^2-\gamma_i\alpha_i^2}{(\gamma_r^2+\gamma_i^2)(\alpha_r^4+\alpha_i^4)}\right] \qquad (9)$$

where

$$\gamma^2\equiv\alpha_r^2+j\alpha_i^2$$

$$\gamma\equiv\gamma_r+j\gamma_i$$

The coefficient of equation 9 may be regarded as the loss which would occur if the currents were resistance-limited. The first term accounts for the redistribution of axial flux at some distance into the tooth, and the second term is a result of the reorientation just beneath the surface. Numerical evaluation of equation 9 indicates that skin effect is of secondary importance for a tooth tip to depth of penetration ratio w/δ of less than about 4. The ratio of w/δ for large turbine generators is generally less than 4; hence, it may be concluded that skin effect does not have a major part in determining tooth loss. Equation 9 was derived on the basis of uniform axial flux. Since the axial flux decreases approximately

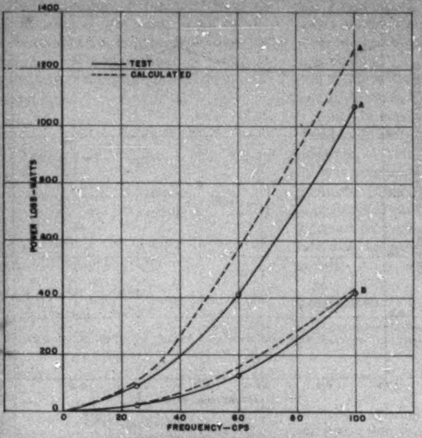

Fig. 7. Comparison of test and calculated losses in model with flux normal to laminations

Curve B—Relative flange shield current

uniformly with depth into the package, the first term should be reduced by a factor of three.

Tests were run to evaluate loss with flux perpendicular to the laminations. First the losses in a stack of laminations 4 by 1.5 inches stacked 1 inch high were measured at varying inductions at different frequencies. The loss in two packages 4 by 0.75 inch stacked 1 inch high were also measured under identical conditions. The loss in these samples and a comparison with the losses evaluated by equation 9 are shown in Fig. 7. These data illustrate the effect of split teeth as well as confirm the method of calculation. Generator end tooth losses were computed by applying equation 9, modified to account for axial distribution, to successive radial increments of the tooth for which the axial field was nearly constant. End finger losses were calculated on the basis of resistance-limited currents.

Effect of Split End Teeth

As was mentioned previously, end tooth losses and temperature rise have been reduced significantly by the introduction of split end teeth. The end tooth is simply slotted, effectively laminating the tooth to eddy currents flowing parallel to the core laminations. Inspection of equation 9 indicates that the loss intensity with resistance-limited currents varies as the cube of tooth width. It would be expected, therefore, that placing one slot in a given tooth would reduce the loss by a factor of 4. The reduction in skin effect tends to offset part of this gain, however.

Fig. 8. Temporary copper shield mounted on stator core flange

STATOR CORE FLANGE LOSS

The dimensions of the stator core flanges of large turbine generators are such that pronounced skin effect occurs, i.e., the dimensions of the flange are large in comparison with the depth of penetration. Under this condition, the flange will act as a shield and will prevent end leakage flux from penetrating the body of the flange and entering the back iron.

In the electrolytic tank, therefore, the nonmagnetic flange was represented as a conductor having zero resistance. The flange current distribution, both radial and peripheral, is obtained directly from the potential distribution in the tank. The flange power loss was computed from this current distribution and the effective flange resistance based on the material resistivity and the known depth of penetration.

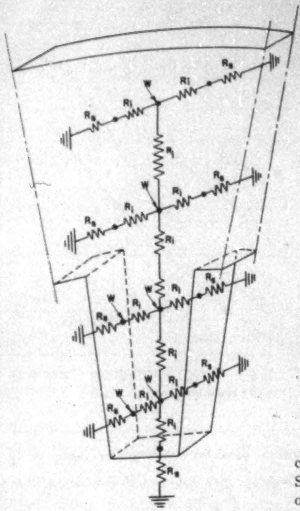

Fig. 10 (left). Thermal equivalent circuit representing end package of stator core

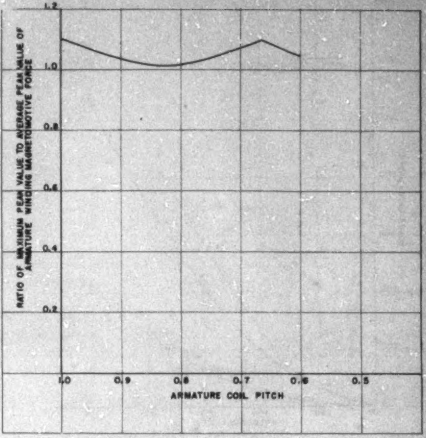

Fig. 11 (right). Variation in ratio of peak to average armature winding mmf with armature winding pitch

Because the nonmagnetic steel flange acts as a shield, the eddy-current loss can be reduced by substituting a material of lower electrical resistivity, or by covering the flange with a highly conducting shield. With constant current flowing in the flange or in the shield, the loss will vary approximately as the square root of the electrical resistivity because of the changing depth of penetration. This theory has been tested by tests on a production generator with a temporary copper shield, or amortisseur winding, located over both core flanges. This temporary shield in place on the flange is shown in Fig. 8.

The generator was tested with the shield in place and, again, with the shield removed. In Fig. 9 is shown a comparison of the relative difference in the stray load loss with and without the shield with the calculated difference in loss. The flange loss is a relatively small part of the total generator input under these conditions, but the comparison of test and calculated results is as close as can be expected.

The shield current was measured by a current transformer located on one of the radial straps. A comparison of test and calculated shield current during short circuit operation is also shown in Fig. 9. The calculated curve does not pass through zero load because of the method of accounting for retaining ring saturation.

Studies were also made of the losses in cast-iron and magnetic steel flanges. Since these do not correspond to surfaces of infinite permeability or zero resistance, it was necessary to represent the surfaces in the electrolytic tank by a network of resistances simulating magnetic conditions in the skin. The losses were found to be larger than in either the nonmagnetic steel or shielded flanges.

The flange losses can be reduced by the use of either a very high resistance or laminated magnetic shield. A magnetic shield of this type must be made from a material of very high resistance or properly laminated so that it is capable of carrying the end flux without large losses being induced in the shield itself. An additional factor of some importance is the effect of the flange or core shield on the magnetic flux distribution in the vicinity of the armature end turns and the resulting armature winding copper loss.

END IRON TEMPERATURE RISE

End tooth temperatures have been calculated using the thermal equivalent circuit, shown in Fig. 10, to represent the end package of laminations. This circuit is based on the usual approximations for 3-dimensional heat-flow problems. The tooth was represented by two nodes, with the appropriate tooth losses injected as equivalent current inputs. The iron thermal resistances are based on the core dimensions and the thermal resistivities of the core material. The surface resistances are based on the surface areas and the surface heat transfer coefficients calculated from known velocities of the cooling medium. The end finger losses are injected at the end surface nodal points.

Comparisons of test and calculated average end tooth tip temperature rises for a range of load conditions and at varying hydrogen pressures are shown in Fig. 3. The test values shown are the average of six thermocouples attached to the outside lamination at the tips of six teeth. The tests were run in the Moss Landing steam plant of the Pacific Gas and Electric Company on units nos. 2 and 5. These units are exact duplicates except that no. 5 has split end teeth. Calculated values shown are based on the methods of calculation outlined in the preceding sections.

EFFECT OF ARMATURE WINDING PITCH

It has been observed on many machines that the end teeth at or near the intersections of phase belts show the highest temperature. It will be shown that this behavior is caused by the variation of the armature winding mmf or by the harmonics of the armature reaction.

The armature winding mmf for a 3-phase generator during balanced operation can be written as

$$F=\frac{4}{\pi}A_{sw}\left(\cos(\omega t-\theta)+\frac{1}{5}\frac{k_{p5}k_{d5}}{k_{p1}k_{d1}}\cos(\omega t+5\theta)+\frac{1}{7}\frac{k_{p7}k_{d7}}{k_{p1}k_{d1}}\cos(\omega t-7\theta)+\ldots\right) \tag{10}$$

where the peripheral angle is measured from the center of a phase belt. Thus, the winding mmf consists of a fundamental sinusoidal term plus harmonics of the fundamental, the magnitudes of the harmonics depending on the winding geometry.

The magnitude of the total mmf at the location of the peak value of the fundamental term may be determined by setting $\omega t=\theta$ in this equation, which is equivalent to riding around on the fundamental term.

Then

$$F'=\frac{4}{\pi}A_{sw}\left[1+\left(\frac{1}{5}\frac{k_{p5}k_{d5}}{k_{p1}k_{d1}}+\frac{1}{7}\frac{k_{p7}k_{d7}}{k_{p1}k_{d1}}\right)\cos 6\theta+\ldots\right]$$

The ratio of the change to the peak value of the fundamental is

$$\frac{\Delta F}{F'}=\left(\frac{1}{5}\frac{k_{p5}k_{d5}}{k_{p1}k_{d1}}+\frac{1}{7}\frac{k_{p7}k_{d7}}{k_{p1}k_{d1}}\right)\cos 6\theta+\ldots \qquad (11)$$

It can be shown by direct evaluation that equation 11 has equal maximum values at the intersections of phase belts in the top and bottom layers in the armature winding. A plot of the ratio of the mmf acting at these points to the average mmf is shown in Fig. 11.

It may be concluded that the variation of end tooth temperature is caused by the variation of the armature mmf. This effect is exaggerated by the fact that the harmonic permeance paths are shorter than for the fundamental. Fig. 11 then indicates only qualitatively the temperature rise variations which may be expected.

Discussion

Richard T. Smith (General Electric Company, West Lynn, Mass.): Mr. Winchester has made a valuable contribution to the study of end losses through a judicious combination of theoretical work and model testing. This approach seems to be the one most appropriate, since direct measurement of generator end losses would be exceedingly difficult to carry out. The attendant problem of end temperature rises can be resolved satisfactorily by temperature measurements in the end region under various load conditions. My company has carried out this work with the help of a full load test base capable of loading the machine under test up to 18,750 kva at any power factor between zero lag and zero lead.

Tests conducted on this base during the past few years have proved conclusively the efficacy of nonmagnetic retaining rings in reducing end temperature rises during leading power-factor operation. In addition, valuable data have been obtained relative to the effects upon temperature rises of changes in materials and geometry of the end region structure.

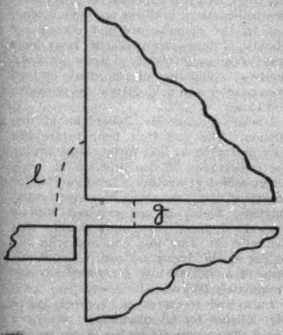

Fig. 12. End leakage flux path

That end losses may be expected to increase with increasing air gap lengths, as are being called forth by design innovations, may be shown qualitatively by reference to Fig. 12. Roughly, $B_l=(g/l)B_g$; thus, for a given per-cent increase in g, there is a somewhat smaller per-cent increase in l, thereby increasing the leakage density B_l for a given B_g.

The effect of field current in causing losses in the end region may be explained as follows: At rated load and lagging power factor the magnitude of the field mmf is sufficient to produce saturation of the magnetic retaining rings, which are then paths of relatively high reluctance, so far as the course taken by armature leakage flux is concerned. In addition, the mmf of the field end turns opposes that of the armature. As the load power factor passes through unity and thence into the leading region, the field current steadily decreases, causing the retaining rings to desaturate. As the retaining rings regain their full magnetic properties, the reluctance of the path of armature leakage flux decreases and the mmf of the field end windings is shielded from the armature. Thus the armature leakage flux increases and is accompanied by rising losses. If nonmagnetic retaining rings are used, or if the magnetic retaining rings remain saturated even at leading power factors, the resultant mmf effective in producing end loss again increases as the power factor passes into the leading region, because of the change in phase relation between the armature and field mmf, so that the losses also increase.

In addition to the work of de Pistoys (ref. 7 of the paper), some of the other contributors to the literature in this field are given in the following references.

E. I. Pollard (Elliott Company, Ridgway, Pa.): Fig. 13 illustrates the typical construction used by my company at the ends of the stator core on turbine generators and other large synchronous machines. The fingers supporting the ends of the stator teeth are made from nonmagnetic steel bars. The fingers are in turn supported by clamping plates of magnetic steel. Magnetic steel is used in the rotor retaining rings of turbine generators. Narrow radial slots are punched in the teeth in the packages of laminations at the ends of the core, thus dividing the width of the tooth in two from the standpoint of the amount of end fringing

Table I. Maximum Temperature Rises

Ampere Conductors per Inch	Tooth Tip Rise	End Finger Rise	Clamping Plate Rise
1,020	36	25	52
590	21.5	17.5	25.5

flux linked by each section of the tooth, in the same manner as described in Mr. Winchester's paper. Fig. 13 shows a 7,500-kw turbine generator; the photograph was taken in 1946, when this construction was made our standard. Prior to this it was used by another manufacturer.

We tested two hydrogen-cooled 20-megawatt preferred standard turbine generators in 1953. To obtain sufficient kilovars for full load overexcited at zero power factor on one machine, the other was operated underexcited at zero power factor at practically zero field current in air. Thermocouples were placed on the tooth tips at the ends of the teeth, on the tips of the end fingers, and at the bore of the end clamping plate. Temperature tests were made at 0 power factor underexcited at two loads; at about zero field corresponding to 1,020-ampere conductors per inch of mean air gap periphery and at a lesser load corresponding to 590-ampere conductors per inch. Maximum temperature rises were as shown in Table I.

Since the first test was made at about zero field in air, these temperature rises are quite moderate. The tests indicate crudely what rises might be expected as the armature ampere-turn loading is increased as would be the case with direct cooling, remembering that other design changes such as longer air gaps associated with direct cooling operate to increase the amount of flux fringing into the ends of the teeth and hence their temperature rise. However, it is obvious that by dividing the end teeth into more than two sections by using more than one slot per tooth, the end tooth tip temperature can be controlled for machines of any size and loading.

After correlating these tests with a similar one made on a smaller machine, it became apparent to us that the temperature rise of the magnetic steel clamping plate would become excessive at some rating and current loading beyond our present experience, and we concluded that a copper magnetic shield over the outer surface of the clamping plate would be the most practical solution. Mr. Winchester's account of the use of a copper magnetic shield on the clamping plate is therefore most interesting to me. However, I fail to see the need for making the clamping plate of nonmagnetic steel when it is sheathed with copper, particularly when the core laminations are made of grain-oriented steel. It would be of interest if the author would report the kilowatt gain in load loss on short-circuit test realized by the use of this copper shield at full load current.

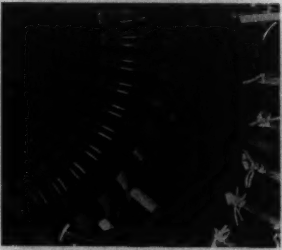

Fig. 13. Typical construction used at ends of stator core

The subject of stray losses in rotating machinery is a most interesting one. Mr. Winchester is to be congratulated for this excellent paper, which contributes to our quantitative knowledge of several of the sources of these losses.

Lee A. Kilgore (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The author is to be congratulated on a rather thorough analysis of end zone losses in a large generator. I went through similar calculations with less mathematics 22 years ago and arrived at the same conclusions regarding split teeth in the end package; and such split teeth have been used on large water-wheel generators built by my company since that time and have been employed on the inner-cooled turbine generators where their use is absolutely essential.

I arrived at a somewhat different conclusion regarding end flanges or end plates. The author concludes a copper shield is best and that a nonmagnetic steel is better than magnetic. We have found that a silicon iron plate gives very low loss although a laminated shield which can handle the end zone flux is the ideal answer. With either the copper shield or the nonmagnetic steel end plate extremely high currents flow on the inner edge. The author says a small fraction of the end winding current, but the end winding current may be 50,000 amperes. It would be interesting to know what current Mr. Winchester did find flowing in the inner edge of the core flange. Even 10 per cent of end winding current in the bottom 2 inches of this plate might give over 100 watts per cubic inch and quite high temperatures. With a heavy continuous copper plate suitably shaped, the flux may be crowded out of the end plate and in spite of tremendous currents on the inner edge the temperatures would not be excessive. These copper shields have been used for a number of years by the ACEC Company of Belgium. However, a properly designed laminated iron shield can take care of this end zone flux with a minimum loss and would seem the ideal answer. The author indicates the tested values of surface temperature on the ends of the teeth, Fig. 3. The equivalent thermal circuit, Fig. 10, indicates at least an approximate method of determining the average if not the hottest temperature of the teeth. It would seem that these internal temperatures should be considerably higher than the surface temperature and it would be interesting if the author can give such figures for the full kva under excited range for the conventional construction.

G. W. Staats (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): Our company has had very favorable experience with flux traps of silicon steel, wound around the stator coil ends so as to form circumferentially laminated rings. Use of these rings in a fully supercharged generator described last year[1,2] has aided in keeping the temperature rise of the disk spring holding the individual tooth finger plates, as measured by thermocouples, down to 22 degrees centigrade at full load in 5 pounds per square inch hydrogen pressure on a machine designed for operation at 30 pounds per square inch hydrogen pressure. These tests have been described in a current paper.[3]

The author's attention is directed to a paper in the British literature[4] which discusses stray loss in some detail, paying particular attention to the end region. The paper contains a bibliography of 25 references, of which perhaps six are directly concerned with stray losses in the end region. The spirited discussion of this article is also worth reading.

R. L. Winchester: Mr. Smith's comments add significantly to the understanding of several of the important factors of the problem. A considerable amount of very practical data have been obtained on the full load test base of the Medium Steam Turbine Department at Lynn, Mass. The availability of such equipment makes possible a thorough full-scale evaluation of design innovations over the entire range of load conditions.

The use of nonmagnetic retaining rings results in a considerable reduction in end losses and temperature rise. All 3,600-rpm generators, 50,000 kw and larger, have been built by my company with magnetic retaining rings, and it is expected that this practice will continue until the problems attendant to the manufacture and control of quality of large, nonmagnetic rings have been adequately solved. I agree with Mr. Smith's explanation of the effect of load power factor and field current on generator end losses.

I wish to thank Mr. Pollard for his discussion. The end iron temperature rise data presented by him further substantiate the importance of the problem in large, direct-cooled generators. In answer to his questions, it is our conclusion that a nonmagnetic flange is not required with a properly designed conducting shield. The reduction in stray loss obtained with the copper shield during no-load, short-circuit tests of a 125,000-kva generator was approximately 25 kw.

I also wish to express my appreciation to Mr. Kilgore for his discussion. We have found that a periodic review of our knowledge of fundamental problems is desirable in order to maintain a quantitative understanding of these problems through the years of design improvements.

We are in substantial agreement with Mr. Kilgore's statement that a magnetic shield would seem to be the ideal answer to the problem of flange loss and temperature rise. However, a number of factors influence the choice of the type of shielding to be used. Among these are: 1. the co-ordinated mechanical design of stator frame flange, flange shield, and armature end windings and winding supports; 2. the design of a magnetic shield to minimize loss in the shield itself; and 3. the effect of the flange shield on the magnetic field near the armature end turns and the resulting extra loss in the end winding copper. Either type of shield could be used, but the conducting shield appears to us to be the better solution. We will continue our evaluation of the problem as we gain more experience with large, direct-cooled generators.

I have explored Mr. Kilgore's calculations on shield current and loss. Using Mr. Kilgore's figure of 5,000 amperes' shield current, we calculate a little less than one-third of the figure of 100 watts per cubic inch. Furthermore, if this loss is simply integrated to obtain total shield loss, adding in 50 per cent additional to account for return currents on the outer periphery, the total is found to be approximately 9 kw. This is quite low for the flange loss in a machine with a rating corresponding to Mr. Kilgore's example. This loss, dissipated over the entire shield area, would result in a very moderate temperature rise.

We have no recent operating experience with magnetic iron flanges in large, modern, hydrogen-cooled generators. Since about 1924 all of our large machines have been built with nonmagnetic stator frame flanges. Since that time we have had very satisfactory operating experience with regard to end heating in these machines.

It is well known that the internal stator tooth temperatures must be higher than the surface temperatures, since the heat is generated internally and a temperature gradient must exist in order for the heat to flow to the surface. We have examined the internal end tooth temperatures in great detail and, in the cases which we have studied, have found that, although the internal temperatures are somewhat higher, the operating margins are more than adequate for the expected service.

Finally, I would like to thank Mr. Staats for his comments. Mr. Staats and his associates are to be congratulated for the completion and successful operation of their supercharged generator.

In closing, it should be noted that a general solution to the end loss problem applicable to the machines of several manufacturers is simply not possible because of the close relationship with the details of design and construction. It is possible, however, to obtain an understanding of the losses in a given design. Through the work described in this paper and continuing efforts, we have obtained a quantitative understanding of the magnitude and distribution of end losses in our generators.

Correlation of Temperature Measurements on D-C Armatures

D. D. GERBETZ
ASSOCIATE MEMBER AIEE

J. S. EWING
MEMBER AIEE

Synopsis: The significance of the usual temperature measurements made on d-c armatures is somewhat vague, and the amount of published data on the subject is limited. This paper presents the results of a large number of laboratory tests showing the correlation among several different methods used for measuring temperatures on d-c armatures. It is believed that temperature measurements made with embedded thermocouples, read through slip rings, greatly enhance the validity of the correlations reported in this paper. Based on the data presented, it is concluded that temperature measurements made by careful resistance methods are more reliable and more nearly approximate the hot-spot values, than those made by thermometers. In the interest of brevity the scope is limited to the measurement of temperatures on the armature of d-c machines.

IT WAS evident from the number of discussions of two previously published papers[1,2] that some of the points under consideration were controversial and that additional experimental data would be most helpful toward a better understanding of the problem involved. The purpose of these papers was as follows:

1. To propose a revision of Table I of the American Standards Association Standard for limiting observable temperature rise.[3]

2. To present test data correlating thermometer and resistance rise to hot spot temperature.

3. To introduce the method of measuring temperature by resistance as a recognized standard.

Shortly after the presentation of these papers, the authors were afforded the opportunity to make a rather exhaustive study of temperature measurements on five experimental motors. The motors involved were classified as General Industrial Motors, drip-proof enclosed, continuous duty, 60 degrees centigrade rise using class-*B* insulation. These motors were self-ventilated with the fan exhausting out the end opposite the commutator. With regard to temperature measurements, these motors were felt to be representative of the present day general-purpose d-c motors. The nominal horsepower and speed rating for the motors involved are shown in Table I.

Experimental Procedure

A trial setup was made in the laboratory with thermocouples submerged in an oil bath and connected through a set of slip rings to an indicating instrument. After several modifications of the brush assembly and the junction location, it was found possible to read temperatures with a 1-per-cent (%) accuracy for a wide speed range of the slip ring assembly. With this experience as background, it was concluded to install embedded thermocouples along the armature conductor for all five sample motors. The location of these thermocouples are indicated in Fig. 1. The thermocouple leads were brought out through an axial hole in the end of the shaft to a slip ring assembly which could be directly connected to an indicating instrument. A photograph of the slip ring assembly connected to one of the sample motors is shown in Fig. 2.

The technique of making armature resistance measurements for the purposes of obtaining temperature rise was completely reviewed. After a number of trial runs had been made, a procedure was evolved

Table I. Ratings of Sample Motors

Horsepower	Rpm	Volts
40	1,750	230
60	1,750	230
100	1,750	230
150	1,750	230
200	1,150	230

Paper 55-106, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing November 22, 1954.

D. D. Gerbetz and J. S. Ewing are with the Reliance Electric & Engineering Company, Cleveland, Ohio.

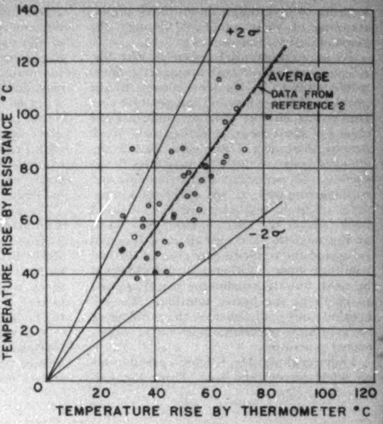

Fig. 3 (right). Resistance versus thermometer

such that measurements could be made quickly and, if necessary, repeated with a high degree of accuracy. For a description of the precautions and procedures used in making resistance measurements see the Appendix. It should be pointed out that procedures and technique outlined in the Appendix are not original with the authors, but are listed for the purpose of emphasizing the necessity of following an organized, yet practical, procedure when making resistance measurement on low-resistance armatures if accurate results are desired.

With regard to thermometer measurements, the procedure employed is the one outlined in the AIEE test code for d-c machines standard.[4]

To accumulate a large mass of data the five motors listed in Table I were subjected to a series of heat runs. Besides rated load and speed, heat runs were made on these motors at four different speeds below base speed, and at each speed several runs were made with different load settings. It would be well to emphasize that on each heat run, armature temperatures were measured by 1. A series of thermocouples located along an armature conductor; 2. Resistance measurements of the armature circuit between brushes; and 3. Thermometers located on coil heads.

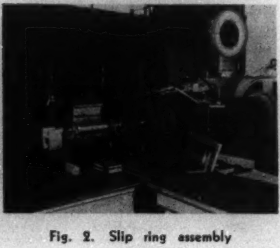

Fig. 2. Slip ring assembly

Presentation of Data

Figs. 3 through 6 show graphically the correlation of the three different types of temperature rises obtained from test data, namely:

1. Resistance versus thermometer, Fig. 3.
2. Hot spot versus thermometer, Fig. 4.
3. Hot spot versus resistance, Fig. 5.
4. Resistance versus average by thermocouples, Fig. 6.

In conjunction with the plotting of test results, it was assumed that each type of temperature measurement bore a direct relationship to the other method of measurement indicated on the graph. For example, a fixed ratio exists between the rise by resistance to the rise by thermometer. These ratios were calculated for each test and averaged. The average lines, or average ratios, are indicated on each graph. Also, the standard deviation factor σ, or rms error, was calculated for each set of data and the lines representing the two σ values are plotted on these graphs. These lines tend to bracket 95.44% of the possible test points. The average ratio and the rms error values corresponding to Figs. 3 through 6 are tabulated in Table II.

Results

The correlation of rise by resistance to thermometer indicated in Fig. 3 has several significant aspects. First, the average line shows excellent agreement with that published in Fig. 1 of reference 2. This is indicated by the dotted line on Fig. 2. It was upon that data that the recent revisions of Table I of reference 3 were based. The data of this paper therefore add additional support to the validity of this latest revision, which permits rises to be evaluated from resistance measurements as an optional method.

Secondly, it is rather obvious that the correlation from individual measurements could be in considerable error, as indicated by the dispersion of the test points and the values of the standard deviation factor σ. The reason for this scattering of test points results, for the most part, from the errors associated with thermometer measurements. This point will be made more evident after the remaining figures are discussed.

Fig. 4 shows the relationship between hot spot and thermometer. It is believed that this correlation is a better index than any previously published of hot spot based on thermometers. The explanation lies in the method of measuring hot-spot temperatures. It was felt that the number of thermocouples located in the armature and the measurement of temperature while the armature was rotating greatly improved the accuracy of measurement. Again, the dispersion of test points is believed to be partly a result of the inaccuracies of thermometer measurements.

The correlation between hot spot and resistance is shown in Fig. 5. These data are also felt to represent better the correlation between hot spot and resistance than previously published data because of thermocouple measurements and also be-

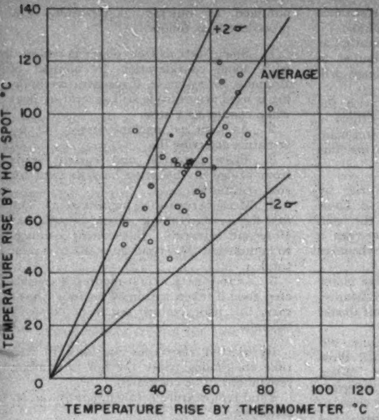

Fig. 4 (left). Hot-spot versus thermometer

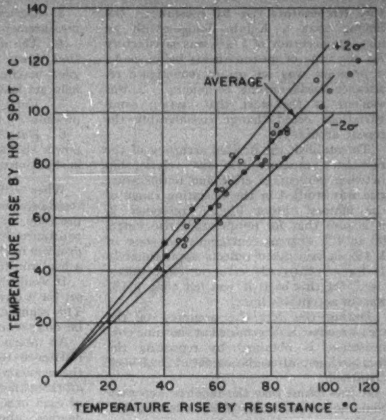

Fig. 5 (right). Hot-spot versus resistance

cause of the pains required in taking the resistance measurements. It is evident also that the dispersion of the individual test point has been greatly reduced over those charts where thermometers were indicated. A further examination of Fig. 5 substantiates the statement made by previous discussers that resistance measurements more nearly approximate the hot spot than do thermometers measurements, and that therefore more weight should be given to resistance measurements.

In Fig. 6, the rise by resistance is shown plotted against the average rise of the conductor of calculated from the thermocouple measurements. The average rise was calculated by plotting the thermocouple temperatures against the developed length of the conductors, as was done in Fig. 1, calculating the area underneath the temperature line, then dividing the area by the abscissa of the diagram. The correlation indicated in this figure is excellent; the rise as measured by resistance equals the average rise of the conductors, which is as it should be. The relatively small dispersion of the test points, as compared with previous test results, must be considered good.

Table II. Correlation of Temperature Measurement

Figure No.	Average Ratio	Rms Error, %
3	$\frac{\text{TR* by resistance}}{\text{TR by thermometer}} = 1.44$	±22.9
4	$\frac{\text{TR by hot spot}}{\text{TR by thermometer}} = 1.53$	±22.5
5	$\frac{\text{TR by hot spot}}{\text{TR by resistance}} = 1.10$	± 6.62
6	$\frac{\text{TR by resistance}}{\text{Average TR based on thermocouples}} = 1.00$	± 4.1

* Temperature rise.

Conclusions

1. Additional data correlating indirect temperature measurements with hot-spot temperatures and correlation of the various methods of indirect measurements among themselves have been presented in Figs. 3 through 6.

2. An indication of the range of possible errors for an individual measurement is indicated in Table II.

3. The correlation between resistance and thermometer shows excellent correspondence with that published in reference 2 and also with the revised Table I of reference 3.

4. The use of distributed thermocouples measured while the armature is rotating greatly enhance the validity of the data reported here over that previously published.

5. Based on the data presented, rise by resistance measurements can be made which show considerable improvement over those made by thermometers for the following reasons:

(a). The rise by resistance more nearly approximates the hot-spot temperatures as indicated by a comparison of Figs. 4 and 5.

(b). The accuracy of the measurement is strongly in favor of the rise by resistance. A comparison of Figs. 4, 5, and 6 will bear evidence to this fact.

6. Fig. 6 confirms the obvious conclusion, that the rise by resistance is a measure of the average conductor temperature throughout the machine.

Appendix. Procedures and Technique

Associated with an over-all program of temperature evaluation of d-c motors, a technique was developed to measure arma-

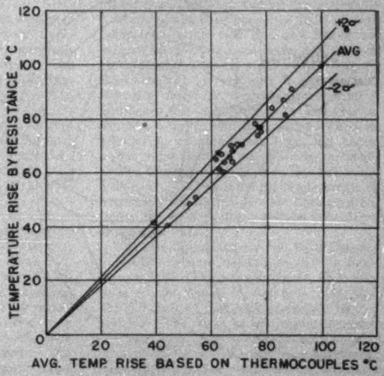

Fig. 6 (right). Resistance versus average from thermocouples

ture temperature rise by resistance. Believing that a Kelvin bridge with an absolute accuracy of 1/4% was satisfactory for the type of measurements being made, a program was set up to investigate resistance measurement technique. It was evident at the start that certain small variations could change considerably the repeat accuracy.

To establish the desired accuracy of the resistance measurement the relationship between percentage error and temperature rise was studied in the operating range of the motors. From Fig. 7, reference 2, it is seen that for temperature rise range, 60 to 100 degrees centigrade, an error of 1/4% in resistance reflects approximately 1 degree centigrade error in temperature rise. On this basis it was felt that 1/4% was an acceptable limit.

During the test the accuracy of the measurement is determined at the time cold resistance is obtained by repeating the measurement after the armature has been disturbed.

It was found that the required accuracy could be obtained only if the following precautions were taken:

1. Armature must be in the same position for hot and cold measurements.
2. Current and potential leads of the bridge must always be placed on the same commutator bars for hot and cold readings.
3. Bridge leads must be designed for surface contact.
4. Supply battery must have sufficient charge and capacity to maintain maximum sensitivity of the bridge galvanometer.

Immediately after a heat run is shut down, time, in addition to accuracy, is of the essence. It is very desirable to get a first resistance measurement within 40 seconds. This can be accomplished only if a well-organized procedure incorporating most of the following steps is followed.

1. The bridge must be adjusted prior to shut-down to read the approximate resistance expected.
2. Rapid stop should be done by dynamic or regenerative braking or other means.
3. Commutator bars used for resistance measurement should be clearly marked.
4. The use of two or more operators at shut down with the work distributed to gain maximum manpower efficiency will help get fast readings.
5. Until testers are familiar with the procedure a few trial runs will help them.
6. Data sheets, timer, bridge, and manpower should be organized before machine is shut down.

When calculating temperature rise by resistance it is very important to know precisely at what temperature the cold resistance is measured. This becomes a problem in the testing department whenever a heat run follows a check test.

It would be desirable to leave the motor set for a day before taking cold resistance. This is not always practical to do but should be done whenever possible.

An alternate method to determine cold resistance temperature is to install three thermometers on the coil surface. When all three thermometers are within 3 degrees of each other and none are more than 10 degrees above room temperature, the average reading is the value to be used for cold resistance. This limitation may vary according to the physical design and should be checked for individual cases.

The setup and procedure for measuring cold resistance are as follows:

1. Four holes are drilled in the commutator as shown in Fig. 7. Hole diameter to be such that fit will be snug with the plug fully inserted.
2. The bridge leads are plugged into the holes. For details of the plug and leads see Fig. 8.
3. Measure resistance and scribe a line on the motor shaft and bracket.
4. Remove leads, disturb armature, and reset to scribe line.
5. Replace leads and measure resistance.
6. Repeat the reading obtained in step 3 within 1/4%.

If the reading is not repeated, check items 1 to 4 listed under precautions.

Hot resistance is measured immediately after shutdown and first readings are obtained as quickly as possible. The procedure is as follows:

1. Start timer as time power is removed with some consideration to method of stopping, for example, if regenerative braking is used armature is still generating heat while coming to a stop.
2. As soon as machine stops, line up armature to scribe line.
3. Place potential and current leads from bridge in the same bars as used for cold resistance.
4. Measure resistance immediately. The first five or six readings should be taken at 10-second intervals. Subsequent readings to be taken at 20-second intervals to 6 min. total.
5. As to timing, a first reading is considered good if taken within 30 seconds; however, this may average out to be 40 to 45 seconds.

By plotting resistance rise back to zero time on semilog paper the hot or running resistance can be computed.

Total temperature is calculated by the relationship

$$T\text{ hot}=\frac{R\text{ hot}}{R\text{ cold}}\times(234.5+T\text{ cold})-234.5$$

Temperature rise is obtained by subtracting ambient temperature from the total temperature.

Discussion

E. H. Meyers (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The problem of obtaining accurate readings of temperatures on machine parts has received considerable study in the last 15 years. The authors have done a fine job of developing a correlation of the results obtained by different methods of temperature measurement, and have justified the belief that consistent and accurate readings of temperature rises by the resistance measurement method can be obtained, provided sufficient care is taken.

However, it appears that the authors have also shown that, as desirable as the resistance measurement method is from the standpoint of accuracy, it is not very feasible for normal shop production testing. This is particularly true in the case of the manufacture of large machines where a given design might be built only once. For instance, it is doubtful that the production department would be receptive to the suggestion that the motor should sit for a day before taking a cold resistance or that holes should be drilled in certain commutator bars.

It appears doubtful that the importance of temperature rises on most commercial machines is great enough to justify the special methods and precautions listed by the authors. Most customers would not be willing to bear the resulting extra expense. In the case of temperature tests using thermometers it must be admitted that some of the thermometers will not give accurate values of temperature on the shutdown reading, but when the highest value of these temperatures is used from a large number of thermometers in similar locations, it is probable that the error would not be more than a very few degrees at the most. Considering the margin provided in accepted standards and the possible additional margin between the guarantees and the actual values on the machine shipped, this error becomes relatively unimportant. This is particularly true in large machines for special applications. For instance, rod mill drives may require exceptionally low-impact speed drops, tandem cold mills for steel require special speed regulations for the driving motors, blooming mill drives must have abnormal overload capacity; such requirements naturally result in low-temperature machines.

We hope that the authors' conclusions will not be interpreted to mean that the resistance method described is recommended for normal machine production tests. The methods appear to be an excellent laboratory procedure where unusual accuracy is justified, but should be limited to rather special tests.

E. C. Watson (Westinghouse Electric Corporation, Buffalo, N. Y.): The paper is a valuable contribution to the art. The authors state that the scattering of the test points is due to the errors associated with thermometer measurements. Was a series of experiments run on the same machine and under as near duplicate operating conditions as possible and, if so, what correspondence was obtained on these results? My experience has been that on such repetitive tests the thermometer measurements can be duplicated within a 2-degree-centigrade (C) rise when identical test procedures are followed. Does the rise by resistance follow a similar pattern?

Note 1. Limiting temperature rise by resistance proposed by AIEE Standards Coordinating Committee No. 4

Note 2. Limiting temperature rise by resistance proposed by AIEE Subcommittee on D-C Machines (ref. 1 of the paper)

M. A. Baker (General Electric Company, Erie, Pa.): The authors are to be congratulated on their fine paper. Their average ratio of rise by resistance to rise by thermometer correlates very well with the experience of my company in tests made on medium- and large-sized d-c machines over a number of years.

I should like to give some of the data presented to the Rotating Machinery Committee by my company in 1944. These data were originally presented to support the AIEE Committee No. 4 proposed addendum to ASA Standard C50 (ref. 3 of the paper) to increase the rise by resistance on both class-*A* and class-*B* insulated armatures and were again presented at the AIEE Summer General Meeting in 1949. While these data are not recorded in the *Transactions*, they will be found in the 1949 minutes of the D-C Machinery Subcommittee.

Fig. 9 shows the results of armature-heating data taken on 23 machines ranging from 3-kw at 1,200 rpm to 300-kw at 900 rpm with voltages ranging from 60 to 250. Both open machines with radial ventilation and axially ventilated dripproof machines were included. The ratio of rise by resistance to rise by thermometer varied over approximately the same range with both types of ventilation and enclosure. The maximum ratio of rise by resistance to rise by thermometer was 2.31 and the minimum ratio was 1.07. The amazing fact, however, is that the average of ratio of rise by resistance to rise by thermometer is 1.44, exactly the same as that determined by the authors.

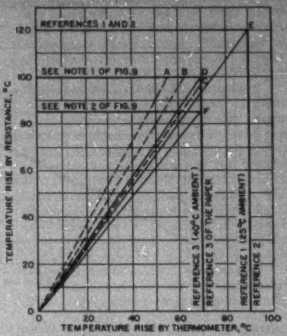

Fig. 10. Class-B machines continuous-rated

A—Maximum ratio from tests on 17 machines
B—Mean ratio from same tests
C—Minimum ratio from same tests
D—Proposed by AIEE Standards Co-ordinating Committee No. 4
E—Standard for traction machines[1,2]
F—Proposed by AIEE Subcommittee on D-C Machines (ref. 1 of the paper)

Similar data were taken on a number of class-*B* insulated d-c armatures, and on 17 heat runs made on machines ranging from 80 kw at 3,600 rpm to 5,000 horsepower at 100-rpm with voltages ranging from 220 to 600. Both the open and the enclosed types of machine were tested. These data were presented as Fig. 10. The maximum ratio of rise by resistance to rise by thermometer on these limited tests was 1.79 and the minimum 1.37. The average ratio of 1.57 is very close to the new ASA Standard C50 Table I (ref. 3 of the paper) and only slightly higher than that observed by the authors.

Many of the data presented in 1944 were taken from production tests and rise by resistance test techniques were not as well established then as they are today. Fig. 11 shows the rise by resistance to rise by thermometer ratio for d-c armatures from a number of tests made within the last year on dripproof motors and generators with axial ventilation ranging from 1 to 150 horsepower. To simplify the plotting on probability paper, the data were limited to 50 heat runs. Data which appeared erratic or questionable in any way were discarded entirely, so these results must be considered as selected data.

The minimum ratio of rise by resistance to rise by thermometer is 1.29 and the maximum is 1.79. The mean ratio of 1.48 is very close to the ratios in the new ASA C50 Table I and to the data presented by the authors. The ratios at one sigma deviation are 1.32 and 1.64 which represent an rms error of ±10.8%. It must be remembered, however, that these were selected data and

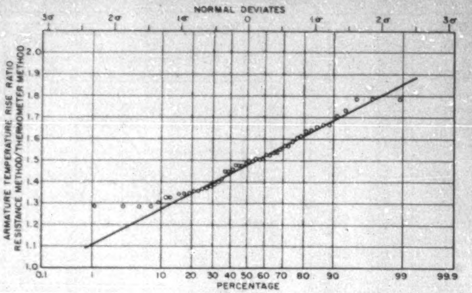

Fig. 11. Armature temperature rise ratio of resistance method to thermometer method. Results of 50 selected tests on 13 d-c self-ventilated motors ranging in size from 1 to 150 horsepower

greater variation would have been observed if all data had been used. The correlation, however, with data obtained 11 years ago and with that presented by the authors is remarkable.

M. L. Schmidt (General Electric Corporation, Fort Wayne, Ind.): The authors should be congratulated on the description of two excellent testing methods and on the proof in Fig. 6 that accurate data are obtained. It is inconceivable that there could be any significant bias or large errors in the measurement of temperature rise by resistance or the thermocouple measurements when two methods of measuring the average temperature have the 1-to-1 ratio and small dispersion shown in Fig. 6.

What I want to discuss, however, is not the test techniques or the test results but the presentation of the data. I have studied this subject of temperature measurement for many years and find that all authors, including myself, have made one of two assumptions in their statistical presentation. Some have assumed with the authors that the errors (in the statistical sense) are proportional to the temperature rise, while others have assumed that they are independent of the temperature rise. These two assumptions result in two sigma lines which diverge from the origin or which are parallel to the average line respectively.

Actually it is known that some of the errors, such as the error in taking readings and probably most of the instrument error, are independent of temperature rise and that other errors such as those due to variations in construction, ventilation, and loss distribution are proportional to temperature rise. Since some of the thermal resistances are not constant, some of the errors are probably a more complex function of temperature rise but it is unlikely that they are important over normal temperature ranges. If it is assumed that the error has two components, one independent of rise and the other proportional to rise, the equations for determining the statistical constants are

$$K\Sigma\frac{x^2}{\sigma_c{}^2+x^2\sigma_c{}^2}=\Sigma\frac{xy}{\sigma_v{}^2+x^2\sigma_v{}^2}$$

$$\Sigma(Kx-y)^2=N\sigma_c{}^2+\sigma_v{}^2\Sigma x^2$$

$$\Sigma x^2(Kx-y)^2=\sigma_c{}^2\Sigma x^2+\sigma_v{}^2\Sigma x^4$$

$$\sigma x=\sqrt{\sigma_c{}^2+x^2\sigma_v{}^2}$$

where

K = coefficient of average line $y=Kx$
σ_c = constant component of the standard deviation
σ_v = variable component of the standard deviation
σ_x = standard deviation at any point x
N = number of test points

Obviously an iterative method is the only practical method of solving the equations for K, σ_c and σ_v but in my experience the convergence is very rapid so that one iteration is all that is necessary. When this is true, the computation time is about three times that for the simpler assumptions mentioned earlier.

To show how this different approach affects the results, the proportionality factor for rise by resistance over rise by thermocouple is 0.932 instead of 0.929 and the rms error in per cent at 90 C hot spot rise is 3.66 instead of 4.94%. The first effect is negligible, being less than the probable error of the average, but the second reduces the spread of the two sigma limits from 19.8 to 14.6 C.

This is almost a limiting case, as Fig. 12 shows that the limit lines are almost parallel to the average line. Fig. 13 which is the average temperature rise by thermocouple plotted against hot-spot rise shows the slightly diverging limit lines which are obtained when the temperature-sensitive errors are approximately the same magnitude as the constant errors.

Although the sample size is too small (only five machines) to have the results mean much, there is at least an indication of the precision of the hot-spot readings in these data. The only readily recognizable sources of constant error in the thermocouple readings are tester and instrumental errors. Fig. 6 proves that there is negligible temperature-sensitive error with respect to the copper adjacent to the thermocouple, so let this unknown standard deviation be σ_{tc}. Then

$$\sigma_{HS}=\sigma_{TC}$$

and the constant portion of the average thermocouple deviation when compared to hot spot

$$\sigma_{CTC}=\sqrt{\frac{\sigma_{TC}{}^2}{8}+\sigma_{TC}{}^2}$$

For this data the value of σ_{HS} is 2 C which

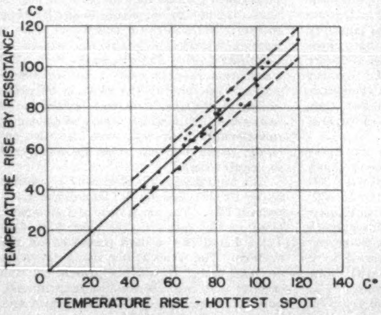

Fig. 12 (left). Temperature rise by resistance and hottest spot

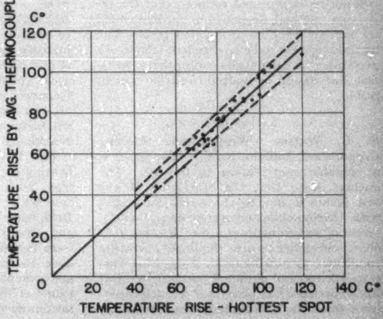

Fig. 13 (right). Temperature rise by thermocouple and hottest spot

is a little larger but quite comparable to the reported 1% calibration accuracy.

Although a comparison of rise by thermometer and rise by resistance was the primary reason for this work, the equations just shown could not be used for the thermometer data. The variations proportional to temperature were so wide and the number of points so small that σ_C^2 as calculated was negative, which is impossible. If we disregard the fact that thermometer rise must be zero when hot-spot rise is zero, and draw a line which best fits the points, it would indicate 19 degrees by thermometer when the hot spot is zero. This large apparent bias could occur because the low-temperature points were predominantly from one machine while the high-temperature points were from another machine. I should like to ask the authors if this is the case.

R. Lamborn (General Electric Company, Erie, Pa.): The authors are to be congratulated on their findings, which prove once more the superiority of the rise-by-resistance method of temperature measurement. I believe in this method. The design group with which I work has used it for more than 25 years; not as an alternative method, but as the best method for determining temperature rise. Possibly some may not be aware that the AIEE standard covering railway and other transportation equipment,[1] has specified the rise by resistance method since 1937. For the past 18 years the rise by thermometer method has had no official sanction in connection with the rating of this class of electric rotating equipment. Others also have found that when proper care is exercised, the rise by resistance method gives the designer more honest and consistent information than he ever obtained from thermometers.

I should like to enlarge upon one feature in the paper. The statement is made that by plotting resistance rise back to zero time on semilog paper the hot or running resistance can be computed. Since cooling curves are exponential in character, and since an exponential curve plots as a straight line on semilog paper, the inference might be made that in determining the so-called zero time temperature it is necessary only to lay a straight edge on the cooling curve points and read the intercept on the *Y*-axis.

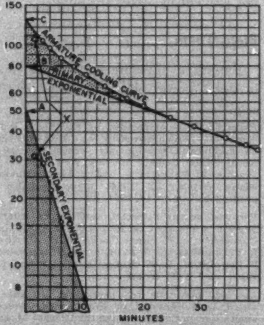

Fig. 14. Armature cooling curve analysis. Note how secondary exponential replot spots bad test point X and yields correct zero time rise C by adding intercepts A and B

Regrettably, the authors did not include a graph in their paper to show just how this worked out. In the case of transportation motors and generators, where the machines are forced somewhat harder than general purpose motors in terms of temperature rise and ventilation, the typical cooling curve is actually quite far from being a simple exponential. It seems to have two major components. The primary or longer time component has to do with the cooling rate of the armature core and windings as a unit, and upon this is superimposed the more rapid secondary exponential, probably in a large measure representing the equalization in temperature between the copper winding and the mass of the armature core.

It is of interest to note the characteristic shape of such a compound exponential when plotted on semilog paper (see Fig. 14). It is neither a straight line nor a composite of two straight lines. However, the difference between the compound exponential curve and the straight line representing the primary exponential will plot as a straight line on the same semilog paper. This fact and an appreciation of the basic concept of the relative values involved will frequently permit the engineer to discriminate between good and poor test data, and to estimate more accurately the true zero time temperature rise even though only one or two test cooling curve points may have been taken during the critical first few minutes after shutdown.

To some this will seem like a complicated procedure just to find the temperature of a motor winding. I believe, however, that to learn how to get the greatest possible performance from a given amount of material, designers will turn more and more toward this sort of approach to the problem.

I should like to ask Mr. Ewing what precautions were found necessary to obtain accurate running temperature readings from thermocouples operating through slip rings?

REFERENCE

1. GENERAL PRINCIPLES UPON WHICH TEMPERATURE LIMITS ARE BASED IN THE RATING OF ELECTRIC MACHINES AND OTHER EQUIPMENT. *AIEE Standard No. 1*, Feb. 1954, par. 1–11.

John Cybulski (Naval Research Laboratory, Washington, D. C.): The paper contains excellent procedures. It was not clear whether the temperature rise obtained by the thermometer method was gained by the subtraction of the ambient temperature from the reading or reflected some correction (in percentage or degree) by virtue of the fact that a thermometer was employed. It should be indicated in the paper that the hot-spot data were obtained by one of the thermocouples if this was the case. Was the thermocouple which provided the hot-spot data for the five machines located in a similar position in each, and did it consistently indicate the highest temperature?

Some statistical procedures were applied to experimental data obtained on five different horsepower rated machines. However, it is desirable to know the total number of heat tests taken and how many test points, identified for each machine, were used in the construction of Figs. 3, 4, 5, and 6. One would assume that the temperature rise data were selected equally from all the machines and employed for all the various temperature ratios taken. This does not appear to be the case if the number of points on Figs. 3, 4, 5, and 6 particularly are indicative of the number of tests used.

It is stated in the paper that the experimental instrumentation employing thermocouples enabled temperatures to be read with a 1% accuracy. What does this mean in relation to the accuracy of the heat test data obtained? What is the variance of this experimental error? Was a similar evaluation made under control conditions for the experimental error of resistance measurement employing a Kelvin bridge with an absolute accuracy of 1/4 %? Was a similar evaluation made using a thermometer?

It is expected that a statistical analysis of the thermometer readings and temperature ratios from each machine should firmly establish the contribution by the thermometer toward the scattering of test points. In particular, such factors as the absolute accuracy of the thermometer, the effects of the rounding off of thermometer readings, the "errors" in placement of the thermometer (thermometer is confined to the vertical position and the size of the machine determines accessibility to some extent) and the time lag for a reading all contribute to the total "measurement" error. This assumes that the same personnel took part in each method. One suspects that placement error and the response time are the major factors.

It appears that if placement could be improved and an analysis made of the inherent time lag of a thermometer some means may be developed for compensating the delayed thermometer reading. This would be analogous to the extrapolation to zero time as now accepted for the primary and secondary exponentials evidenced by the present cooling curves.

Unquestionably, the success of the thermocouple and average resistance measurements is attributed to the short time (after shutdown) necessary for good data to be obtained. If thermometers could be placed accurately and if they responded as quickly, they might be equally reliable.

D. D. Gerbetz and **J. S. Ewing**: The authors appreciate the comments and contributions made by the discussers. Mr. Meyers has pointed out instances where temperature rise is not the prime concern in certain designs because of application, and where objections might be raised to taking heat runs. Since some production departments already observe temperature rise by resistance, the added work would represent a minor modification of their test procedure. We feel the greatest gain by measurement of temperature rise by resistance is reflected in engineering information, since rise by resistance more nearly reflects the average thermal characteristics of the armature, and the value of temperature rise measured is nearer the hot spot, with the measurement more accurate.

The ability to repeat temperature measurements on the same machine serves as a good check on the accuracy of temperature measurements, as Mr. Watson suggests. We have made several repeat tests using the resistance measurement, and found that we could repeat within 2 degrees even with a different group of technicians making the test.

The data presented in Mr. Baker's discussion is a fine contribution which we are happy to include as a part of the discussion in this report.

Mr. Schmidt has shown another approach to the evaluation of the errors. In the interest of simplicity, in this report the percent error was assumed to be constant. The temperature rises from the heat runs were in general over the same range for each machine.

Mr. Lamborn points out that the cooling curve is not a straight line on semilog paper. His comments clarify what may have been misleading. He has shown an excellent method of plotting back to zero time. The curve shown indicates a first reading approximately 90 seconds after shutdown. We have found that the average time required to take a first reading is about 40 seconds, but if this for some reason required a longer time, Mr. Lamborn's method would be very useful. The precaution found necessary to obtain accurated temperature reading from *T/C* through slip rings was to introduce cold junctions in the *T/C* circuit and control the temperature of each junction. Also it was necessary to insure good brush contact.

Referring to Mr. Cybulski's discussion, for each method of temperature measurement, the ambient was subtracted from the total temperature to obtain temperature rise. The thermocouples were placed in nearly the same position for each machine. However, for each test the hot spot did not occur in the same place.

The point of view taken in this paper was to accumulate as much test data as possible over a range of machine sizes, and to correlate the data independent of the machine from which it was taken. Because of laboratory loading it was impossible to obtain an equal number of heat runs on all machines, so that some of the data may be weighted by some machines more than others; however, it was felt that the mass of data would result in good averages.

With regard to the accuracy of the thermocouples and the Kelvin double bridge, on actual heat runs, several checks indicated that we maintained our experimental limits of 1% for thermocouples and 1/4 of 1% for the Kelvin double bridge. A similar evaluation for thermometers was not made.

We agree with Mr. Cybulski that the accuracy of the thermometers could be improved by careful laboratory technique and data processing, but the care and work involved normally would not be justified in the light of the accuracy that may be obtained by resistance measurements. Not only would thermometers have to be placed accurately and respond quickly, but a number of them would have to be used as was indicated in Mr. Myers' discussion.

Effect of Shock and Vibration on Relays

AIEE COMMITTEE REPORT

Synopsis: The Project Committee has undertaken to survey the industries on their experience with the effect of shock and vibration on relays, made field and laboratory tests, and prepared a series of conclusions based on the survey and tests. It has not attempted at this time to present a universal cure for the eliminating of the effect of shock and vibration.

THE Project Committee was formed in the winter of 1950 to study the matter of relay vibration and shock resistance and methods of designing and installing relays to minimize the effect of shock and vibration. The need for such studies came from numerous cases where vibration or shock caused unwarranted protective relay operations. The complexity of the problem was fully realized as the Project Committee gathered available information, conducted tests, and coordinated the results. The studies made by the investigators have produced several interesting and valuable conclusions but have also introduced other questions yet to be answered.

Scope and Procedure

Because of the broad field of vibration and shock affecting the relays it was thought necessary to limit the study to include only the type of protective relays used in trip, control, and alarm circuits used in the power application field. The telephone-type relays were included only whenever they were part of the protective scheme. It was recognized that the design of a shockproof and vibration-resistant relay is unavoidably tied in with the construction of the panel the relay is mounted on, thus the effect of switchboard design is also considered.

The industry-wide survey to gauge the importance of the problem was also within the scope of the project. It was thought that an analysis of the survey will furnish some information as to types and construction of relays where difficulty may be encountered. The field and laboratory tests, where under controlled conditions the performance of the relays can be observed, were an important part of the study.

Survey

The electric operating companies were surveyed by questionnaires prepared by the committee and 64 operating electric utility companies were contacted. Of the 30 replies received, 28 reported 126 cases of relay operation caused by shock or vibration within the past 10 years. The analysis of these replies indicates that approximately 53 per cent of the cases were caused by shock and 47 per cent of the cases were caused by vibration. Further breakdown of the vibration shows that 80 per cent of the vibration originated from rotating machines whereas 20 per cent of the vibration was caused by transients such as passing trains, trucks, or others. Most of the difficulties reported due to shock occurred where relays were mounted on hinged panels. Some were experienced by relays in cabinets attached to circuit-breaker frames. Accidental bumping of relay panels accounted for a number of tripouts. Steel panels appeared more troublesome than the other types. No special relay construction could be singled out from the survey to prove that it is more susceptible to vibration or shocks. Auxiliary seal-in contacts appear to be responsible for some of the circuit-breaker operation caused by shock imparted to the relay. For this reason it was thought that an increased separation of main relay contacts may not prevent incorrect tripping.

Field Tests

Extensive measurements were made in steam power plants by two operating

---

Paper 55-97, recommended by the AIEE Relays Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1954. Manuscript submitted October 22, 1954; made available for printing November 18, 1954.

Personnel of the Project Committee on Effect of Shock and Vibration on Relays of the AIEE Relay Committee: L. F. FERRI, *Chairman*, A. W. ADAMS, R. E. CORDRAY, M. A. FAUCETT, T. R. HALMAN, H. F. LINDEMUTH, W. K. SONNEMANN, G. STEEB, R. I. WARD, and C. P. WEST.

The field test data were generously furnished by The Detroit Edison, Ohio Edison, and Commonwealth Edison Companies and the Niagara Mohawk Power Corporation. The extensive laboratory tests were conducted by General Electric Company, The Detroit Edison Company, and by the Electrical Engineering Department of the University of Washington under the sponsorship of the Bonneville Power Administration.

companies. The vibration frequencies and amplitudes were measured on switchboard panels, floors, and walls of power stations. The amplitude of vibration measured on steel panels by light beam type of indicators ranges from 0.2 to 2.2 mils and the frequencies varied from 30 to 190 cycles. At another location using the same type of measuring instrument, it was found that the walls were vibrating at an amplitude which increased with the distance from the floor, and readings as much as 8 mils were taken. These vibrations were transmitted to the switchboard panels and were considerably reduced when the panels were mounted on rubber. In these particular tests it was found that the steel panels had a natural frequency of less than 60 cycles and the amplitude of the vibration showed wide variations.

Laboratory Tests

Laboratory tests were conducted by one manufacturing company, one operating utility company, and the electrical engineering department of one university. The tests were mainly centered on determining the effect of shock on relays. The controlled shock was applied either by a hammer of varying weight released from different heights and hitting a fixed panel in pendulumlike fashion or by moving hinged panels through a given angle by various weights suspended on a cord from the panel through a series of pulleys. The acceleration of the panels and in some cases of the relay parts was measured or calculated and the contact bounce observed and graphically recorded. Because of the many factors influencing the tests, only general statements can be made when summarizing the results. It appears that the shock necessary to close the *a* contact of the relay cannot be defined by acceleration alone but rather by the product of acceleration and duration. It was also found that the magnitude of displacement caused by shock is proportional to the momentum and independent of the kinetic energy. It also did not appear to make any difference whether the panel was hit by a wooden or rubber mallet.

The construction of the relay has important influence on shock resistance. The clapper-type relays are generally more sensitive to shock whereas the plunger-type relays are relatively immune to shock caused by a horizontal blow. It was also observed that the shock sensitivity of the clapper-type relay varies with the position of the hinge pin with reference to the plane of the panel the relay is mounted on. For hinge-pin position perpendicular to the plane of panel, the clapper-type relay appeared to have the greatest shock resistance. The shock sensitivity of the relay with potential restraint or polarizing coil is increased if the restraint coil is de-energized.

Factors that reduce the false operation of relays are:

1. Increasing contact gap settings improves shock resistance in most cases. The amount of improvement varies with the other parameters such as a relay time which increases with gap setting. As stated before, however, the shock sensitivity of auxiliary or seal-in contacts may nullify any benefit obtained from gap-spacing increases.

2. Increased armature torques for a given relay setting improve shock resistance of all relays tested. Increased armature torque requires greater mechanical or electric restraining torque for a given relay setting. The increased restraining torque in turn improves shock resistance. Increasing restraining torque without corresponding increase in the armature torque would also result in better shock resistance relay but would reduce relay sensitivity.

3. Modification in backstop construction will result in reduced shock sensitivity. Solid backstop results in contact bounce but backstop arrangements such as ball and sleeve or other nonbounce combinations showed a consistent improvement in shock resistance over other backstop and armature variations, especially in the panel tests.

4. In general it was found that felt washers between backstop and contacts did not increase permanently the shock resistance of the relay. However, in some other instances felt-tipped backstop increased the resistance.

The changing of the natural frequency of the relay-moving element or armature has considerable effect on the shock necessary to cause false operation of the contact. The addition of mass lowers the natural frequency and an increase of spring torque raises the natural frequency. Relays with lower natural frequency are more likely to respond to shock-produced vibrations which are predominantly in the range below 100 cycles per second. The relay case and the cradle absorb a major portion of the shock applied at the door or to the panel.

Investigation of relay mountings on hinged panels reveals that harmful shock caused by slamming can be controlled by mechanically limiting the panel-closing speed. It was also found that the so-called rubber shock mounts of relays where the relay frame was mounted on rubber and the rubber in turn attached to the switchboard panel reduced the sensitivity of the relay to vibration by a ratio of 12 to 1 in the case tested, but the shock resistance was also reduced by a ratio of 2 to 1 if the shock was applied directly to the relay case.

With the hinged panel, the energy stored in rotation and translation before the impact did cause false tripping. Assuming a clockwise rotation of the contact to close upon impact of the panel, the moving element of the relay can either coast (panel hinged right-hand) or bounce on the backstop and coast (panel hinged left-hand). Thus, no conclusive statement can be made that the door hinge on one particular side will be best for all relays which may be mounted on the door. The position of the contact arm with respect to the plane of the panel appears to influence the shock resistance of the relay.

Instruments Used

There are a large number of instruments available in the industry to measure shock and vibration but it was found that only a few were applicable to meet the restrictive conditions encountered. In other cases the investigators were limited in their budget allocated for the study and the more costly instrument could not be purchased. For vibration measurements it was found that instruments using a crystal pickup and electronic amplifier furnished the most satisfactory result. The light beam type of vibration indicator also appeared to be suitable.

Different types of instruments were used for measurements of shock. The accelerometer consisting of a crystal and an amplifier were used by one laboratory. In another case a small slug-tuned coil was used as displacement pickup. The variation of the coil inductance affected the signal output of an oscillator which was amplified to supply a graphic recorder. A device consisting of a bank of leaf springs with graduated stiffness so mounted and connected that for each spring there is a certain acceleration and that is sufficient to open a contact and actuate a gas tube indicator has also been successfully used. In general it was found that the available measuring devices had to be modified to be suitable for measuring the effect of shock and vibration on relay parts under investigation.

Methods of Mitigation

On the basis of field and laboratory studies it appears that shockproof and vibration-resistant relay installation is the joint responsibility of the panel and relay designers as well as to a certain extent of those who install switchboard panels.

In designing switchboard panels and metal-clad switchgear, the following are a few of the provisions which might reduce the possibility of accidental relay operation caused by shock or vibration:

1. Use slate or composition panels where heavy shock or vibration is expected.
2. Brace steel panels by horizontal and vertical webs to add stiffness.
3. Insert shock- and vibration-absorbing layers between panels and base foundations. Similar provision can be made for wall braces. Unusual service conditions where abnormal vibration, shock, or tilting are expected require special consideration[1] and are outside the scope of this report.
4. Avoid mounting shock-sensitive relays on steel doors.
5. Provide rubber mount between relay and panel.
6. Provide door checks to control speed of closing and opening of hinged panels.

It should be noted that provision 5 is effective only in improving shock resistance if the shock is applied to the switchboard panel, but it may reduce it if the shock is applied direct to relay case.

It also appears that certain changes in relays would increase the shock resistance of the relays. Some of these suggested changes are as follows:

1. Improve backstop construction.
2. Increase restraining spring torque.
3. Increase air-gap spacing between disk and magnets.
4. Increase contact gap spacing.
5. Design clapper-type relays so the armature hinge is in a position with reference to the mounting plane to assure the greatest shock resistance.

Conclusions

1. Vibration and shock problems are real with the electric industry. Each cause appears to be of equal importance.
2. Relays on steel panels are more susceptible to vibration and shock than relays mounted on panels such as slate or composition.
3. Almost all types of relays have been reported to operate by vibration or shock, however, some relays are more sensitive than others.
4. Hinged armature (clapper-type) relays are more susceptible to shock whereas plunger-type relays are less likely to operate.
5. Some methods are available to mitigate the effect of vibration on relays. These methods can be grouped in two classes: improvements in relay design and changing in mounting. Both have been proved to be effective in overcoming the effect of vibration.
6. Shock to relays could be caused by straightline motion right angles to the panel, by motion parallel to the panel, by rotary couples applied to the panel, by rotary couples applied to the relay and by rotary couples produced by the operation of a hinged panel section.
7. Shocks resulting from the foregoing causes may be violent enough to cause relay operations and there are certain methods available to mitigate but not completely eliminate the effect of shock. These methods have been grouped in several classes: improvement in relay design, panel design, relay mounting, and modification of electric circuits.
8. The location of door hinges (left or right) will have some effect of the shock sensitivity of certain types of relays depending on the position of the contact arm.
9. Hinged armature relays can be redesigned with counterbalanced armature or with twin contacts and pivot centrally located between contacts which may eliminate the effect of shock on the relay.
10. Electric circuits may be modified so that the tripping circuit requires the closing of two independent contacts and by arranging these contacts to be in different planes.

◆

Discussion

H. C. Barnes (American Gas & Electric Service Corporation, New York, N. Y.): The committee is to be congratulated upon the completion of a fine report on a very difficult subject. Considerable ingenuity must have been required to obtain the necessary data to reach a conclusion. The material should be of great assistance to the utility engineer in laying out panels as well as to the relay designer.

The statement that "The shock sensitivity of the relay with potential restraint or polarizing coil is increased if the restraint coil is de-energized" is certainly a true one. The slightest shock even to a rear side sheet of a steel panel will cause contact closure. Normally, this is not a problem since restraint is present when the line is in service. However, it can be a problem where line side potential devices are used. These relays usually initiate second or third zone tripping through an auxiliary timer. If the contacts should close because of shock or vibration, when restraint is off, they will quite often weld because of the arc from the timer current which is drawn on the slow bounce of the contacts. Normally this does not happen because of an *a* auxiliary switch being open in the circuit breaker under the condition when the line side potential devices are de-energized.

However, this is dangerous when the breaker is out for maintenance and is closed with the disconnects open. Welding on the bounce could cause the breaker to trip and injure the maintenance man. It could also result in delay in restoring the breaker to service if no relay man is available. This can also be true if bus side bushing potential devices are used.

A worse situation could again occur under the maintenance condition where separate breaker failure relaying is provided. Should this bounce and weld, it could result in tripping an entire bus. One solution is to provide plunger-type overcurrent relays to monitor the circuit breaker rather than use auxiliary switches. These would not be picked up because no current was flowing. This is a reasonable application anyway since one of the reasons for breaker failure is the failure of the breaker to interrupt, under which condition the *a* auxiliary switches would be open and would nullify the breaker failure relaying.

Another serious case from vibration is that of the sensitive ground directional relay in the carrier start circuit. These tend to vibrate open, particularly if extreme sensitivity is used. On 250-volt d-c applications, there is often enough resistor current to cause these contacts to weld. This results in false tripping of the remote end of the line for an external fault since the contact cannot open to start carrier. Care in assuring sufficient contact wipe usually can overcome this. Also the situation is improved if the low threshold setting is avoided.

The problem of shock is likely to become greater. The trend toward economy in control buildings results in less clearance between panels. Since these spaces are often used as aisles, the relays are more apt to be bumped by ladders, pieces of conduit, crates, or whatever may be brought into the building. This is particularly true where the doors are arranged such that the space between the relay panels becomes the natural aisle. Location of critical relays high on the panel is a good preventative although not a 100-per-cent solution since they can still be kicked or bumped during such operations as replacing light bulbs. Where additional horizontal stiffening of steel panels is required, the relay mounting studs can often be used to clamp stiffening angles.

M. A. Bostwick (Portland General Electric Company, Portland, Oreg.): The committee report is both thorough and complete. However, it appears that attention may have been directed to consideration of the relay's moving contacts, neglecting spring-mounted stationary contacts.

We have successfully avoided undesirable relay operations by limiting minimum spring tensions and contacts gaps. But in one instance, we experienced an incorrect operation caused by vibration of the spring-mounted stationary contacts! The source of the vibration was a slow-moving logging train just outside the substation. This experience may be of interest to others as it directs attention to the stationary contacts which may also be a source of trouble.

A. E. Flink (Ohio Edison Company, Akron, Ohio): This is a very interesting paper and shows the need for more care in the installation of relays. Too often no attention is given to the shock and vibration which may be present when relay panels are installed. Vibration and shock do not help the bearings and jewels in any relay. Choice of a better location for relay panels can do much to reduce incorrect operations.

I have found that low restraining torque is the most troublesome and the most difficult to overcome. These relays may not operate for normal conditions but will operate for transient conditions such as bringing a machine up to speed. By determining the setting before a relay is bought, a range can be chosen so that the maximum restraining spring torque can be used. By sacrificing some sensitivity we have also been able to overcome small amounts of vibration.

The use of fast clearing and reclosing times makes it necessary to reduce rather than increase the contact gap spacing. For the last few years we have been reducing the gap spacing wherever possible. This makes the relays more sensitive to shock and vibration, but if it is not done, the control scheme may not function properly.

Donn C. Achtenberg (The Detroit Edison Company, Detroit, Mich.): The Project Committee is to be congratulated for a much needed job well done. The need for more information on the effects of shock and vibration is great.

The Detroit Edison Company has developed several shockproofing methods for various relays. These were developed partly from past experience and partly from results of tests made for the purpose of obtaining information for the Project Committee work.

On one clapper-type auxiliary relay another restraining spring is added to the one which is installed by the manufacturer. As manufactured, this relay usually has a pickup of about one-half its rated voltage. The addition of the shock-proofing spring raises the pickup to about rated voltage. For this reason, coil circuits are designed so that double-rated voltage is applied for pickup and then some kind of dropping circuit is provided to drop the voltage to be rated. On this type of relay we feel that counterbalancing the armature would be very beneficial.

One pilot-wire relay uses a polar-type element to which the contacts are attached. On this relay the contact spacing is very close. To help reduce false tripping caused by shock on this relay, the whole polar-type element is suspended on a spring arrangement within the relay case. We believe that this type of shockproofing is very desirable because it helps absorb shock and vibration both on the panel and directly on the case of the relay.

An overcurrent relay which works on the rotating disk principle is also shockproofed. On this relay, the moving contact is a beam which is unbalanced when the overcurrent element engages a gear to rise up and hit the beam. To prevent this beam from bouncing closed, a fixture is attached to the frame of the overcurrent element. The fixture is attached so that it projects directly over the beam and prevents it from operating until the overcurrent element moves over to engage the gear.

In general, we feel that if the proper measuring devices were available much valuable information could be obtained. We agree with the committee's conclusions especially numbers 9 and 10. On number 9, it is felt that, in addition to balancing armatures on clapper-type relays, it should be desirable to mount the relays within the case so that the hinged pin is perpendicular to the plane of the panel.

F. R. Bergseth (University of Washington, Seattle, Wash.): The committee has done an excellent job in preparing a report on this subject which has so many diverse ramifications and about which it is so difficult to say anything general. As a result of field and laboratory tests and analysis it may be said that attention to certain rather minor details in design and amounting of relays may result in considerably improved performance from a viewpoint of withstanding mechanical shock and vibration. One or two points mentioned in the report might well be amplified in view of the experience obtained in the laboratory tests at the University of Washington.[1]

The statement is made that the magnitude of displacement of shock is proportional to momentum and independent of the kinetic energy. A casual mathematical analysis of greatly simplified mechanical systems will reveal that the closure of a pair of relay contacts will depend upon the momentum delivered by a blow rather than the kinetic energy contained in the striking object. A multitude of test blows applied to a sample panel on which typical transmission line and bus differential relays were mounted revealed the correlation expected between momentum and relay closure for these more complex electromechanical structures just as predicted from the analysis of the simpler case. In these days, shock is usually thought of in terms of military specification and such terms as 2,000-foot-pounds shock are common and it may be surprising to note the emphasis on momentum rather than energy. It should be pointed out, however, that the military specifications envision a test blow delivered from a specific testing machine and, in this case, the momentum and kinetic energy of the blow are directly related—a specification of energy of the blow specifies the momentum equally well when the test is to be performed by a hammer blow from a given test machine.

In testing relays by means of a falling hammer type of blow, it was surprising to find that the relay performance was substantially independent of the type of cushioning surface used on the hammer—a rubber, wood, or steel surface resulted in approximately the same relay performance. Study of displacement traces made by electromechanical recorders reveals that the principal difference in the blows of a given momentum administered with different hammer faces lies in the higher frequency components. The natural frequency of the relay contact structure is low compared to the higher frequency components of displacement resulting from the use of a hard-faced hammer and little difference is noted in relay performance with these different types of blows.

A word of caution is in order here. The tests were performed at shock levels sufficient to cause false closures but not sufficient to cause relay damage such as shattered cover glasses or broken or displaced relay mechanisms. If shock intensities in these latter levels were used, it is quite probable that the nature of the striking hammer would be of considerable significance in determining the effect of a blow of given momentum. The same remarks might be made with regard to the subject of panel bracing. It was found that additional stiffening of the panel surfaces was of great help in avoiding false relay operations under shock. However, this might be just the wrong thing to do if shocks of destructive magnitudes were involved.

1. A STUDY OF THE CHARACTERISTICS OF MECHANICAL SHOCK CAUSING FALSE OPERATION OF POWER RELAYS. Homer R. Forbes. *Thesis*, University of Washington, Seattle, Wash., 1953.

L. F. Ferri: The Project Committee appreciates the constructive contributions of the discussers to the subject of shock and vibration as they affect relay performance. The experience accumulated by Mr. Barnes, Mr. Bostwick, and Mr. Flink points in great detail and emphasis to the problems which, because of understandable limitations, could only be summarized in the paper. It is very apparent from their discussions that the modern high-speed relays using electromagnetic principles present in some applications a real problem because of their shock sensitivity. This problem should be a challenge to the manufacturer's design engineers. Mr. Achtenberg's solution indicates that in some specific cases modification of the relays will result in higher resistance to vibration. The committee is indeed very grateful to the contribution of Prof. Bergseth and to the fundamental research done in the laboratory under his supervision. His comments with reference to the relays responding to shock under controlled conditions are well taken and point out that some reappraisal of the basic factors may be necessary.

Practical Application of Sag and Tension Calculations to Transmission-Line Design

J. LUMMIS
MEMBER AIEE

H. D. FISCHER, JR.
ASSOCIATE MEMBER AIEE

DETERMINATION of sags and tensions in transmission lines can be greatly simplified when the accuracy of calculation is given its proper weight. It seems seldom to be appreciated that no workable mathematical equation exactly describes a suspended transmission conductor. Even if such an equation were available, inaccuracies introduced by manufacturing tolerances and field conditions would still be appreciable.

As a matter of fact, the exact relation between sag and tension is not an important one because sag, upon which ground clearance depends, is the only tangible and controllable factor. Good practice and regulatory bodies set a clearance below which the conductors must not lie; economy dictates that this clearance must not be exceeded. Maximum tensions are likewise prescribed but practical considerations generally make this a value that, while it must not be exceeded, can only be approximated. Furthermore, maximum tension is dependent upon the simultaneous occurrence of specific values of temperature, wind, and ice which from experience are known to produce safe designs but are nevertheless supposititious. As a matter of fact, because of the vibration problem, it is seldom practical to design a line for the full allowable maximum tension in any case. Thus emphasis is placed on methods of design and construction which will produce fixed clearances without exceeding safe values of tension.

In view of these limitations, methods will be shown which will produce a design within the practical limits of accuracy. The limitations of these approximate methods will also be shown as well as more precise methods which must be used under certain circumstances.

Inadequacy of Fundamental Assumptions

The usual equations used to describe a suspended conductor are the catenary[1,2] and the parabola.[2] In both it is assumed that the conductor is inelastic and flexible. In the former it is assumed that the distribution of weight is uniform along the curve of the conductor, while the latter is assumed to have its weight uniformly distributed along a horizontal projection of the curve. None of these assumptions is correct. A conductor is elastic so that the distribution of weight, while closely following that of a catenary, is dependent upon tension; furthermore, the conductor is rigid and is supported to some extent by beam action. The mathematics of an elastic and rigid catenary have been approximated[3] and, for a given tension, this curve lies somewhat above the classic catenary. Experiment seems to bear this out. However, it should be noted that any calculation involving clearance requires a transformation from maximum conditions for tension to maximum conditions for sag. Maximum condition for tension occurs during a transverse wind which is erroneously assumed to produce a uniform horizontal force upon the suspended conductor, and if ice loading is present it is assumed to be of uniform linear density throughout the span and from span to span.

The best conductor does not rigidly follow Hooke's law, and bimetallic conductors are notorious for plastic flow. While prestretching improves the elastic properties of conductors, some error arising from plastic flow is inevitable.

Where spans terminate on suspension insulators each span is affected by the action of spans adjacent. Ideally, this influence can be determined analytically but conditions are seldom ideal and some error will usually arise from this factor.

Errors Beyond Control of Design

Regardless of how accurately the design of a span is executed there are errors that are inevitable because of manufacturing and field conditions. Conductor is manufactured with a weight tolerance of ±2 per cent and the diameter tolerance is ±1 per cent, both of which have a direct bearing on the tension and which, since these variations may take place within a span, tend to invalidate the basis of design. Temperature of the conductor during sagging operations cannot be determined closer than ±5 degrees Fahrenheit (F), and this factor, too, is variable in the span. Wind is frequently present during sagging operations, and its influence on the span being sagged is indeterminable. The wind, furthermore, is usually not uniform from span to span and the influence of adjacent spans upon the span being sagged is therefore likewise indeterminate. While the influence of inelastic creep can be controlled with reasonable accuracy under laboratory conditions, it is variable and its control in the field is even more difficult as stringing operations prior to sagging frequently produce an indeterminable amount of creep and consequent error in final tension. Friction of sag blocks can be determined and compensated for if they are of high quality and in perfect working order; however, with the rough handling inevitable during construction the best blocks will vary in frictional characteristics. Finally, the transfer of the conductor from sheave to suspension clamp is done by mechanics whose carelessness or lack of knowledge, particularly where insulators must be offset to compensate for sloping spans, may introduce errors of considerable magnitude.

Equations

In view of the many sources of error outlined in the preceding discussion the catenary is taken as the form assumed by a suspended conductor. With respect to the sag the tension will be on the "safe" side, and with proper modification the equations will be as easy to manipulate as any. The basic equation for the catenary,[1] Fig. 1, is

$$y = C \cosh \frac{x}{C} \qquad (1)$$

Note that the parameter C is directly proportional to the horizontal component of the tension; a constant is the span, which must be constant in all spans separated only by vertical suspension

Paper 54-501, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted June 1, 1954; made available for printing October 6, 1954.

J. Lummis and H. D. Fischer, Jr., are with the Southern California Edison Company, Los Angeles, Calif.

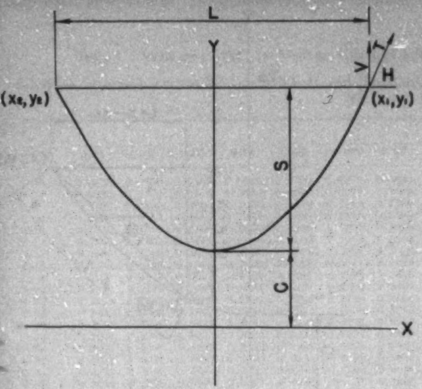

Fig. 1. The catenary

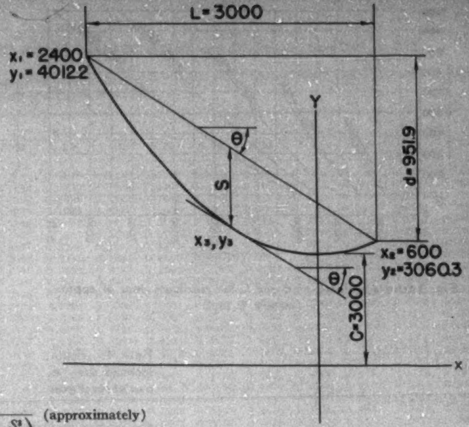

Fig. 2. Example of sag calculation

insulators. In design, therefore, C is the criterion for all sag calculations.

The variations of tension, and therefore C, for changes in temperature and loading may be determined by use of the Thomas charts,[4] Martin's table,[5] or Aluminum Company of America graphic methods.[6]

For a level span the sag is $y-C$, and using the expansion series for the hyperbolic cosine it may be shown that the sag, Fig. 1, in form for easy slide-rule operation, is

$$S=\frac{L^2}{8C}+\frac{1}{6C}\left(\frac{L^2}{8C}\right)^2+0.4\left(\frac{1}{6C}\right)^2\left(\frac{L^2}{8C}\right)^3 \qquad (2)$$

The third term of the series is never significant in the ordinary transmission span as may be seen in the following example where the span is 3,000 feet and C is 3,000

$$\frac{L^2}{8C} = \frac{3{,}000^2}{8\times 3{,}000} = 375.0$$

$$+\frac{1}{6C}\left(\frac{L^2}{8C}\right)^2 = \frac{375.0^2}{6\times 3{,}000} = 7.8$$

$$+0.4\left(\frac{1}{6C}\right)^2\left(\frac{L^2}{8C}\right)^3 = \frac{0.4\times(375.0)^3}{(6\times 3{,}000)^2} = 0.1$$

$$\text{Sag} = 382.9$$

It can be shown that the sag in an inclined span is approximately equal to the sag of a level span of the same length multiplied by the secant of the inclination of the chord. Thus, if θ is the angle of inclination of the chord, the generalized form of equation 2 becomes

$$S=\left[\frac{L^2}{8C}+\frac{1}{6C}\left(\frac{L^2}{8C}\right)^2\right]\sec\theta \text{ (approximately)} \qquad (3)$$

or

$$C=\frac{L^2}{8\left(S\cos\theta-1.33\dfrac{S^3}{L^2}\right)} \text{ (approximately)} \qquad (4)$$

The error arising from the approximations in equation 3 can be seen from the following example; see Fig. 2

$$\frac{x_1}{C}=\frac{2{,}400}{3{,}000}=0.80,\ \cosh\frac{x_1}{C}=1.3374,$$

$$y_1=4{,}012.2$$

$$\frac{x_2}{C}=\frac{600}{3{,}000}=0.20,\ \cosh\frac{x_2}{C}=1.0201,$$

$$y_2=3{,}060.3$$

$$d=\ 951.9$$

$$\tan\theta=\frac{951.9}{3{,}000}=0.3173,\ \sec\theta=1.04913$$

$$=\cosh\frac{x_3}{C}$$

Therefore, $y_3=3{,}147.4$, $x_3/C=0.3122$, and $x_3=936.6$.

Elevation of chord at

$$x_3=3{,}060.3+(936.6+600.0)0.3173=3547.9$$

$$y_3=3147.3$$

$$\text{Maximum sag}=\ 400.6$$

By Equation 3:

$$\frac{3{,}000^2}{8\times 3{,}000} = 375.0$$

$$+\frac{375^2}{6\times 3{,}000} = 7.8$$

$$\text{Maximum sag}=382.8\times 1.0491=401.6$$

The approximate equations for calculating clearances are satisfactory for ordinary conditions. However, if the maximum sag error in a span is to be kept below 1 foot, the curves shown in Fig. 3 will determine the limiting use of the approximate equations. For instance, in a 2,000-foot span with a difference in elevation of 500 feet, C must be 4,000 or greater to enable the use of the approximate equations and still keep the maximum error on the order of 1 foot. The error at the center of the span will always be small, however, with the maximum error occurring near the quarter points of the span. The calculated ground clearances will be greater than the actual clearances in that half of the span near the higher point of support, and they will be less than the actual clearances in the half near the lower point of support. The curves shown in Fig. 3 were prepared from data obtained from calculations comparing the approximate method with the exact method for varying conditions of C, L, and d.

Where the error between the calculated sags (when using approximate equations) and the actual sags exceeds a desirable limit, it will be necessary to use more precise methods. Such a method, Fig. 4, is to determine the level span of which the inclined span is a part, and then use the approximate methods in the level span.

Where l is the length of conductor in the inclined span and x_1 and x_2 are the abscissas of the upper and lower supports respectively, it follows that

$$l=2C\sinh\left(\frac{x_1-x_2}{2C}\right)\cosh\left(\frac{x_1+x_2}{2C}\right)$$

$$d=2C\sinh\left(\frac{x_1-x_2}{2C}\right)\sinh\left(\frac{x_1+x_2}{2C}\right)$$

from which it follows that

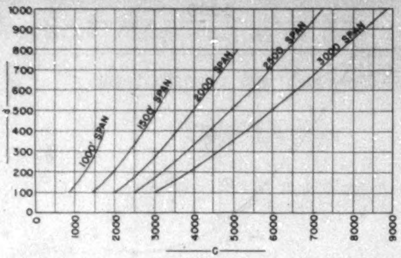

Fig. 3 (above). Limit of d and C for maximum error of approximately 1 foot

$$l^2=\left(2C\sinh\frac{L}{2C}\right)^2+d^2$$

$$x_1+x_2=C\log_e\left(\frac{l+d}{l-d}\right)$$

It then follows that

$$\frac{x_1+x_2}{2C}=\frac{1}{2}\log_e\times\left[\frac{\sqrt{\left(\frac{2C}{L}\sinh\frac{L}{2C}\right)^2+\tan^2\theta}+\tan\theta}{\sqrt{\left(\frac{2C}{L}\sinh\frac{L}{2C}\right)^2+\tan^2\theta}-\tan\theta}\right]$$

$$x_1=\frac{L}{2}+\frac{C}{2}\log_e\times\left[\frac{\sqrt{\left(\frac{2C}{L}\sinh\frac{1}{2C}\right)^2+\tan^2\theta}+\tan\theta}{\sqrt{\left(\frac{2C}{L}\sinh\frac{L}{2C}\right)^2+\tan^2\theta}-\tan\theta}\right]$$

and the level span of which L is a portion is

$$L_e=L+C\log_e\times\left[\frac{\sqrt{\left(\frac{2C}{L}\sinh\frac{L}{2C}\right)^2+\tan^2\theta}+\tan\theta}{\sqrt{\left(\frac{2C}{L}\sinh\frac{L}{2C}\right)^2+\tan^2\theta}-\tan\theta}\right] \quad (5)$$

This equation is entirely too cumbersome for practical use. However, the right-hand term can be set up in tabular or graphic form to expedite the solution. From the foregoing relationships, Table I has been prepared which gives the value of $L_e/(2C)$ for various values of $L/(2C)$ and d/L.

Vertical Clearance

A set of templates representing the curves of the catenary for various values of C may be made for use in the drafting room.[7] These of course would be constructed to the same scale as the profile. The template, when used to locate the structures on the profile, will also indicate the points of critical clearance and the calculations may then be narrowed down to those clearances which are too close to the minimum to rely on template accuracy.

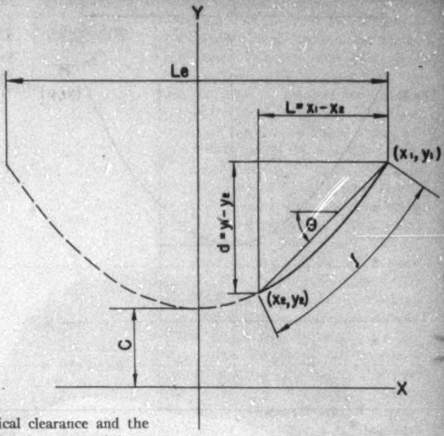

Fig. 4 (right). Inclined span as part of level span

For calculating vertical clearances at points off-center of the span a curve showing the factors K and K' to be applied to the center sag plotted versus the distance from the supports may be used. A curve of this type is shown in Fig. 5. Note that one curve is based on the parabolic value of sag and the other is the correction for catenarian sag. This curve may be used with sufficient accuracy when conditions are such that the approximate equations may be used in other calculations.

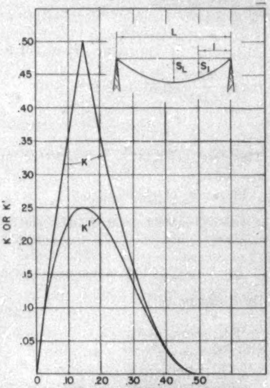

Fig. 5. Sag at intermediate points in span, where

$$S_L=\frac{L^2}{8C}+\frac{1}{6C}\left(\frac{L^2}{8C}\right)^2$$

$$S_l=K\frac{L^2}{8C}+K^1\frac{1}{6C}\left(\frac{L^2}{8C}\right)^2 \text{ for } \frac{l}{L}=0 \text{ to } 0.146$$

$$S_l=(1-K)\frac{L^2}{8C}+K^1\frac{1}{6C}\left(\frac{L^2}{8C}\right) \text{ for } \frac{l}{L}=0.146 \text{ to } 0.500$$

Swing Clearances

Clearances must also be calculated for conductors when they swing out to the side. A typical chart for determining the horizontal displacement and the rise of the conductor, due to a transverse wind, is shown in Fig. 6.

Also clearances between conductor and structure must be determined. This may be accomplished readily with satisfactory accuracy by the use of scale models. A typical model is shown in Fig. 7. To use this model, it is necessary only to calculate the swing of the insulator string and the slope of the conductor at the point of support. Then, placing the various templates in their proper position, the clearance to steel may be scaled.[8]

When the slope of the chord is known, the transverse swing of the insulator string can be computed by assuming that the vertical load imposed by the conductor is the same under wind action as in still air and that the horizontal load is equivalent to the wind force on one-half the sum of the adjacent spans. However, when the action of the wind swings the conductor to the side, the span and slope in the wind plane change[4] and this factor must be taken into con-

Table I. Value of $L_e/(2C)$ for Various Values of $L/(2C)$ Ranging from 0.02 to 0.50, and d/L Ranging from 0.01 to 0.50

Example: Assume L = 1,000 Feet, d = 400 Feet, and C = 5,000. Then L/(2C) = 0.10, d/L = 0.40, and from the Table $L_e/(2C)$ = 0.4894, from Which It Is Found that L_e = 4,894 feet

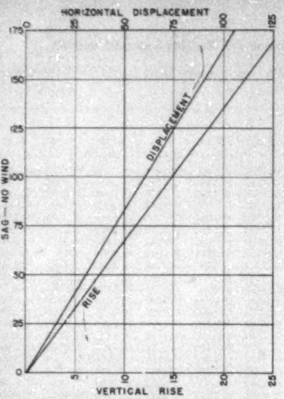

Fig. 6. Swing and rise chart for 605,000-circular-mil (CM) ACSR 30 × 19, 9,000-pound maximum tension at 25 F plus 8-pound wind

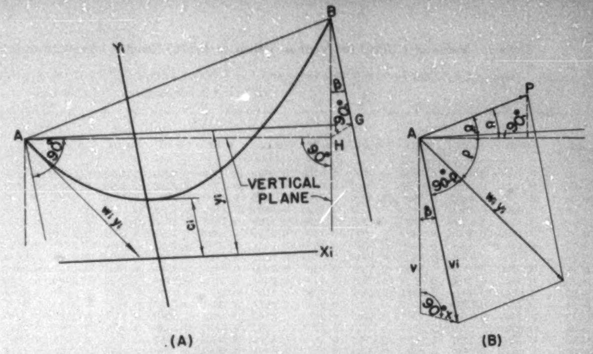

Fig. 8. Conductor lying in the wind plane

sideration for more accurate results. If it is assumed that the conductor under wind lies in a plane whose inclination to the vertical is $\cos^{-1}(w/w_t)=\beta$ where w and w_t are the unit and resultant unit weights of the conductor, the condition shown in Fig. 8(A) results. *AB* is the chord of the span and is common to the vertical and wind planes. *AH* is the span L in the vertical plane, while *AG* is the corresponding span L_t in the wind plane. The differences of elevation, d and d_t are respectively *BH* and *BG*. The conductor in the wind plane is assumed to be a catenary with parameter C_t and y_t is the ordinate at support *A*.

$$L_t=\sqrt{L^2+d^2\sin^2\beta} \qquad \text{(a)}$$

$$d_t=d\cos\beta \qquad \text{(b)}$$

and $w_t y_t$ is the resultant force at *A* from span *AB*.

In Fig. 8(B)

$$\alpha=\tan^{-1}\frac{d}{L},\ \alpha_t=\tan^{-1}\frac{d_t}{L_t},\ \rho=\cos^{-1}\frac{C_t}{y_t} \qquad \text{(c)}$$

The resultant force can be replaced by one component P along the common chord and another, v_t lying along the wind-plane vertical, thus

$$P=\frac{w_t y_t\cos\rho}{\cos\alpha_t} \qquad \text{(d)}$$

$$v_t=\frac{w_t y_t\sin(\rho+\alpha_t)}{\cos\alpha_t} \qquad \text{(e)}$$

The net vertical component acting at *A* is

$$v=\frac{w_t y_t}{\cos\alpha_t}[\sin(\rho+\alpha_t)\cos\beta-\cos\rho\sin\alpha] \qquad (6)$$

or

$$v=v_t\cos\beta-P\cos\alpha$$

where a positive sign indicates a downward force.

The net cross-line horizontal force is

$$x=\frac{w_t y_t}{\cos\alpha_t}\sin(\rho+\alpha_t)\sin\beta \qquad (7)$$

or

$$x=v_t\sin\beta$$

If there is a horizontal angle Δ in the line at *A*, then the cross-line force from span *AB* is

$$x\Delta=x\cos\frac{\Delta}{2}+P\cos\alpha\sin\frac{\Delta}{2} \qquad (8)$$

Equivalent Span

For a given set of conditions each length of span will have a different rate of tension change with change of loading

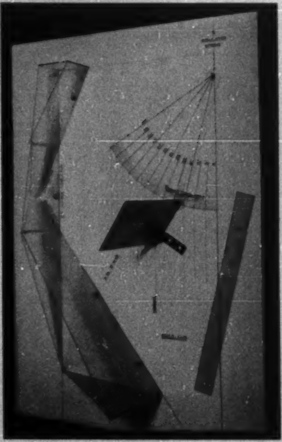

Fig. 7 (left). Model for measuring clearance to tower

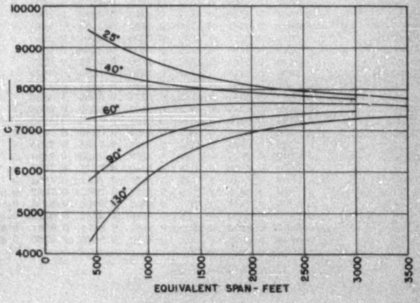

Fig. 9 (right). C Curves for 605,000-CM ACSR 30 × 19, 9,000-pound maximum tension at 25 F plus 8-pound wind or temperature. Thus, where spans are supported on vertical suspension insulators, each span will have an influence on its neighbor such that no span can be considered independently of the remainder of spans in the same section between anchor structures. On the assumptions that the suspended conductor forms a parabola, that equalizing movements of insulators are so small that they introduce no horizontal force from the suspended weight, and that the movement of the insulators can be considered axial to the conductor, Still[9] has developed an equivalent span. This span is the one which will have equivalent characteristics, in so far as tension variation with temperature and loading are concerned, as the series of spans from which it is derived. The equation is

$$L_E = \sqrt{\frac{\Sigma L^3}{\Sigma L}} \tag{9}$$

where

L_E = equivalent span
ΣL^3 = summation of the cubes of the actual span
ΣL = distance between anchor structures of the section under consideration

Using a table of cubes, confining the calculations to three significant figures, and using a slide rule for dividing and extracting the square root, the equivalent span can be determined quickly. However, it is to be noted that generally, as the number of spans increases, the equivalent span approaches the average span, and a little experience will determine when the latter figure may be used. Once the equivalent span is determined for a section of line the value of C for that section can be found from the family of curves in Fig. 9.

The equivalent span method must be used with caution as the error in the assumption made relative to the weight of the suspension-insulator string will cause the clearance to ground to be less than calculated in spans that are shorter than the equivalent, while spans longer than the equivalent will tend to have lessened clearance to lines crossing above. If a section of line contains spans of widely differing lengths heterogeneously distributed, this lack of symmetry will exaggerate the errors, as will be seen in Fig. 10 which compares the true conditions with the condition as calculated by the equivalent span method.

In Fig. 10 the spans have been sagged to a constant value of C=7,650 at 60 F and the true condition is compared with the assumed at 130 F. In Fig. 10(A) the error of the 2-span section is within practical limits of accuracy, and if these two spans are repeated indefinitely in the order 2,000, 1,000, 1,000, 2,000, etc., the errors will remain the same. If these two spans are repeated in the order 2,000, 1,000, 2,000, 1,000, etc., the errors will be reduced somewhat. Thus, where the unequal spans are well distributed, as is the usual case in practice, the errors will be minor.

In Fig. 10(B) the case of unsymmetrical nonuniformity is being approached, although if this 4-span pattern is repeated in any whole multiple the errors will be substantially reduced in all but the end spans of the section. In Fig. 10(C) and (D) the errors are attaining considerable magnitude and where the spans are as unsymmetrically distributed as in the example and if closer determination of clearance is required for critical spans it

will be necessary to resort to the method of distributing insulator swing described in the section on broken wire clearance. In this case it will not be necessary to consider more than four spans on each side of the critical span since more remote spans will have minor influence. The effect of remote spans may be seen in Fig. 10 by comparing *C* values for span 1 in (C) and (D)

The examples chosen have assumed level spans and weightless insulators for simplicity. Where spans are not level the load supported by the insulators will not be proportional to span length, and the weight of the insulators and hardware will increase the clearance error slightly.

When a long section between anchors traverses a mountainous area and then enters a plain, it is likely that there will be an extensive series of long spans followed by a long series of short spans. In this case it may be necessary to grade L_E uniformly from one end of the section to the other. Changes in L_E should preferably be sufficiently gradual to be accomplished by means of friction across the sag blocks during the tensioning operation; otherwise insulator offsets will have to be computed and made.

Calculation of Broken Wire Clearance

At railroads and certain other crossings made on suspension insulators, it is frequently necessary to maintain a specified clearance with the conductor broken in a span once-removed from the crossing. The problem readily adapts itself to solution by converging successive approximations as developed by Cross[10] for determining the distribution of moments in rigid frame works. Others[11] have made the solution from a slightly different approach.

In theory there is no limit to the number of spans beyond the crossing which will influence the tension of the crossing span. However, Table II, which gives the results of a test on a 14-span section, shows that the calculations can be limited to four spans with very little error. Trial by calculation confirms the test results.

Fig. 11 shows the value of *C*, below the normal value, caused by swing of the insulator string, it being assumed that the swing is a reduction in span length. It also shows the rise of the point of support and the restoring component caused by the swing. The system is in a state of equilibrium when the difference in *C* across insulators is equal to the restoring component. Fig. 12 demonstrates this process.

Plastic Flow

Plastic flow takes place in all metals[12] and at high tensions can have considerable effect on sag. For a given set of conditions the flow in aluminum conductors is greater than in copper or steel.[12] The effect is a growth in stressed length, Fig. 13, and consequent increase

Fig. 12. Example of broken wire calculation

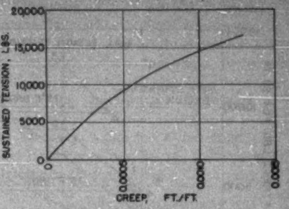

Fig. 14. Typical creep-tension curve for 795,000-CM ACSR. Total creep at 1,000 hours sustained load on unprestretched cable. Nominal ultimate tension of 27,950 pounds

of sag. The amount of flow in unimetallic conductors will vary with the installed tension, the relative tightness of stranding between layers, and the size and number of strands; also service conditions of temperature, degree, and duration of loading. Flow in bimetallic conductors will depend upon the foregoing factors and, in addition, on the proportion between metals, the temperature at time of stranding and the temperature at installation.

The influence of any one of the preceding factors, except tension, is usually small, but if their effect is cumulative the total may be appreciable. In any case it is indeterminate. The total amount of plastic flow in steel-reinforced aluminum cable (ACSR) may amount to 0.20 per cent of the conductor's stressed length; i.e., it may be equivalent to a temperature rise of about 200 F. Obviously this strains the assumptions basic to the equivalent-span principle, and it is equally obvious that a small percentage of error in the assumed total amount of creep can result in considerable error in the magnitude of the final sag.

There are in general use three methods of providing for plastic flow in conductors, each with its advantages and handicaps:

1. String the conductor at an initial tension high enough to provide for all the plastic flow to follow.
2. Prestress the conductor during the sagging operation at a tension high enough, and hold it at that tension long enough to cause all plastic flow to take place prior to final sagging.
3. Combine the two methods; prestress at a moderately high tension for a reasonable length of time, and allow for a moderate amount of plastic flow to follow.

In the first method the initial tension will be high, frequently higher than the maximum design tension, and this will impose undue loads on the supporting

Assumed: All strands snug at stranding temperature, 100 F. Conductor tensioned at 100 F. Maximum design tension at 25 F

structures, aggravate tie-down conditions, intensify vibration troubles, and increase insulator swings at suspension angles, all for an indeterminate time extending into the operating life of the line. Plastic flow is a function of tension, Fig. 14, and because of the large amount of creep it is difficult to determine the final sag with exactitude; large amounts of creep may stretch equivalent-span assumptions beyond reasonable limits. Where sections of line successively sagged are separated only by suspension insulators, an indeterminate amount of plastic flow will take place in the first section before the second section is sagged, and the tensioning operations will thereby be hampered. Likewise, on single-circuit lines where it is necessary to level the three phases for appearance's sake, delay between sagging phases will make the leveling difficult or impossible. However, this method is generally the simplest from the construction standpoint and is frequently used for that reason.

The second method may temporarily overload anchor structures, and they may have to be supported. Tensioning equipment such as winches and cable grips will need to be stouter than normal. The conductor will tend to rise above the sag blocks at lightly loaded towers, and this condition will require precautions to prevent damage to the conductor. The "soaking" time may unduly delay construction operations. However, the advantage of the method is that the conductor, when finally sagged, is in a stable condition so that clearances can be determined accurately and without waste of structures.

The third method offers some of the constructional advantages of the first without unduly sacrificing the accuracy of the second. Somewhat heavier equipment may be required, the conductor may rise above the sag blocks at the most lightly loaded towers, and the sagging operation may be somewhat delayed. However, the anchor structures will usually withstand the tension as a temporary load, and subsequent creep will not generally be excessive; see Fig. 15.

The amount of plastic flow for a given set of conditions can only be determined from test, but the prestretching tension at which subsequent creep will be substantially eliminated can be approximated graphically, although for careful work this should be checked by test of at least 6 months' duration. The following method will give results at least sufficiently accurate to serve as a starting point for a time-elongation test.

If, in Fig. 16, the conductor is prestressed along the curves 1–2 and then sagged at stringing tension 3, the drop in temperature to minimum design value 3–4, together with the imposed maximum loading, will cause the tension to rise to the maximum design value 5. If the prestretch tension has been properly selected, the stress in the aluminum will never exceed the value attained at prestretch; and subsequent plastic flow will not take place. This procedure fails to take the time element into consideration, but if the conductor were to be held at tension 2 for a sufficient time, the results would be as predicted. Time, however, is usually costly, and, since higher tension will produce the same results, the latter element is generally more economical. For the case shown in Fig. 15, tests demonstrated that a prestretch tension of 16,000 pounds held for 10 minutes, reduced subsequent creep to 0.03 per cent as compared to 0.05 per cent for unprestressed conductor.

Since it was assumed in Fig. 16 that the unstressed length was the same for both core and envelope, it is evident that either loose stranding or prestretching at temperatures above stranding temperature will lessen the effect of the prestretch on the aluminum, while the reverse will be true when prestretching is done at temperatures below the stranding temperature.

Field Work

In the final analysis the accuracy of the design is entirely dependent upon

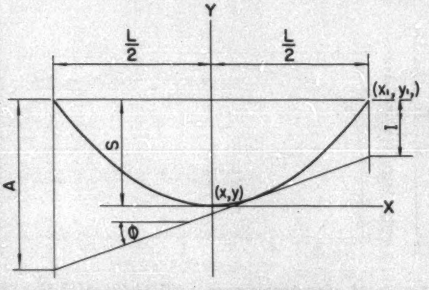

Fig. 17. Method of sagging using unequal intercepts

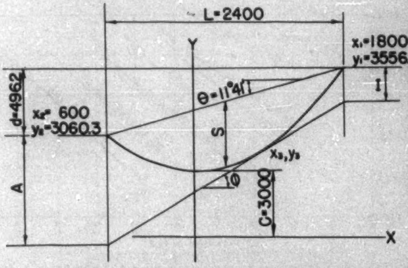

Fig. 18. Example of sagging inclined span

field operations. It is therefore necessary for the designer to prescribe the tensioning procedure. Dynamometers are ruled out wherever the section tensioned consists of more than a very few spans, because such an instrument can give the tension at only one end of the section. For longer sections the sighting method must be used, and this may be done in short spans with naked eye and sight boards, but long spans will require the use of a surveyor's transit.

So far as adjustment of tension is concerned there is no limit to the number of spans that can be sagged simultaneously by the sight method, regardless of the nature of the terrain or amount of friction in the sag blocks, provided that communication facilities are adequate and that the sag blocks are well constructed and have uniform frictional characteristics. The limitations on length of tension section will be determined by construction difficulties, and the optimum length will be reached when the cost of handling the excess conductor pulled from the section balances the savings resulting from fewer temporary anchors. Tension sections 5 miles long are common, and sections of 7 miles have been successfully sagged.

The number of saggers to a section is dependent upon the number of spans to be sagged, the quality of the sag blocks and the tension. It has been found for spans averaging about 1,100 feet, with roller-bearing sag blocks and C below 5,000, every fourth span should be sagged. Where spans average 1,400 feet and C is above 6,000, a sagger in every fifth span is adequate. Best use can be made of the least number of saggers if each conductor of a circuit is put through on identical cycle of tensions. Commonly the last sagger of a section positions his conductor while slacking back from a previously overpulled position. The next sagger, because of sag block friction, will now find his conductor low, and he therefore positions it by tightening, which in turn makes the conductor of the succeeding sagger high, etc. If this order of procedure is reversed at any stage while tensioning the next conductor, the effects of uncompensated sag block friction will be reversed between saggers on the two conductors.

For sagging purposes the conductor can be brought tangent to a line of sight which is parallel to the chord and below it by the amount S. However, it is sometimes difficult and usually inconvenient to establish such a line of sight. A more flexible method of adequate accuracy is to use unequal intercepts at the conductor supports. Consider the level parabola of Fig. 17, where

$$y_1=\frac{L^2}{8C}-y+\left(\frac{L}{2}-x\right)\tan\phi+I$$

$$y=\frac{x^2}{2C}$$

whence

$$\frac{dy}{dx}=\frac{x}{C}=\tan\phi$$

Combining these expressions

$$C=\frac{L^2}{8S}=\frac{A\pm2\sqrt{IA}+I}{2\tan^2\phi} \qquad (10)$$

Solving for S

$$S=\left(\frac{\sqrt{A}+\sqrt{I}}{2}\right)^2 \qquad (11)$$

This equation may be applied to a catenary, see Fig. 18, with considerable accuracy where neither of the factors, I or A, exceeds the other by more than two to one.

The sag by equation 3 is

$$\begin{aligned}\frac{2,400^2}{8\times3,000}&=240.0\\ +\frac{240^2}{6\times3,000}&=3.2\\ \text{Sag}&=243.2\times1.0212=248.4\end{aligned}$$

The true maximum sag for this catenary is 248.2, while the true center sag is 248.1. If $I=175.6$, the line of sight is tangent to the catenary at $x_1=810$ and $A=336.0$. By equation 11

$$S=\left(\frac{\sqrt{175.6}+\sqrt{336.0}}{2}\right)^2=249.3$$

The ratio C/L is usually 3 to 1 or greater and where this is the case it is usually safe to assume that results will be accurate when the ratio between I and A is as high as 4 to 1. However, the normal procedure is the reverse of the preceding example since it is usual to assume a value for I and from this and S compute a value of A which will determine the line of sight. Rearranging equation 11

$$A=(2\sqrt{S}-\sqrt{I})^2 \qquad (12)$$

If the preceding values for I and S are used, then $A=333.8$. These values for I and A are tangent to a catenary for which $C=3,012$, with a true center sag of 247.2 feet.

From equation 11, there follow equations which will facilitate sagging by use of an engineer's transit with methods familiar to cadastral surveyors. It is assumed that the point of observation, or transit, is at I and that the intercept A is at the distant support. The angle of the tangent ϕ, and the angle of chord θ, are considered negative when they are downward from the point of observation; d is negative when the distant point of support is below the one occupied. All other factors are always positive. Since $A=d+I-L\tan\phi$, then

$$S=\left(\frac{\sqrt{d+I-L\tan\phi}+\sqrt{I}}{2}\right)^2 \qquad (13)$$

$$\tan\phi=\frac{d+4\sqrt{IS}-4S}{L} \qquad (14)$$

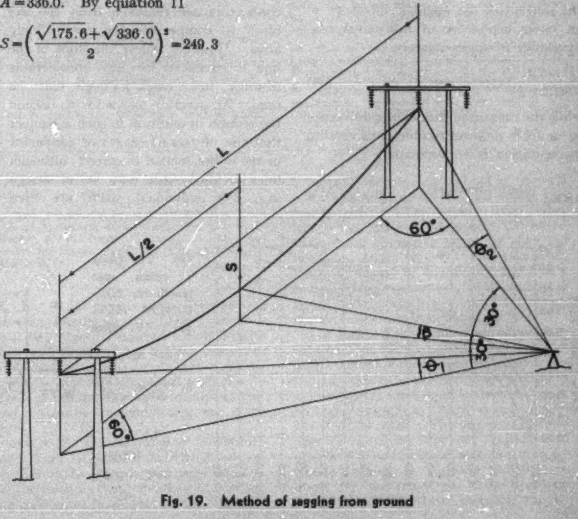

Fig. 19. Method of sagging from ground

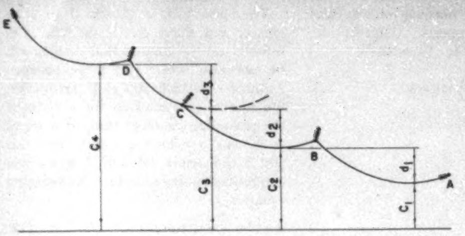

Fig. 20. Series of sloping spans

The preceding methods and equations are to be used when the transit can be mounted on a structure. This limits the method to steel-tower lines, or to wood-pole lines where sag is sufficient to make the observations from the ground at the structure, because mounting a transit on a pole is difficult and in any case a man skilled in the operation of the instrument is not apt to be skilled in climbing poles. For wood-pole lines where the span is too long for the use of sight boards, the transit may be mounted to the side of the line, and the vertical angle to the sag at the center of the span is readily computed. If the transit is placed at the apex of an equilateral triangle with the span as the base, see Fig. 19, it can be shown that

$$\tan\beta = 0.577(\tan\theta_1 + \tan\theta_2) - \frac{S}{0.866L} \qquad (15)$$

If the setup is made for the center conductor and P is the phase separation, the tangent of the angular difference to an outer conductor of horizontal configuration is approximately

$$\frac{P\tan\beta}{0.866L+P}\ \text{(approximately)} \qquad (16)$$

while the tangent of the angular difference to an upper or lower conductor of vertical configuration is approximately

$$\frac{P}{0.866L}\ \text{(approximately)} \qquad (17)$$

In general, the vertical angles will be small and tangents will be less than 0.1, so that slide-rule accuracy is adequate. For the same reason, stadia location of the apex of the equilateral triangle is sufficiently accurate. Nevertheless, the apex angle, regardless of its deviation from true 60 degrees, should be bisected to the nearest minute.

Sagging Sloping Spans

When the transmission line is in steeply sloping terrain, the difference in tension, across a supporting structure may be greater than the sag-block friction can support, and the conductor may tend to "run downhill." Where the unrestrained difference is small, the sagger may compensate for it by using judgment in adjusting the tensions somewhat tight at higher elevations and somewhat slack at lower, depending on the natural swing of the insulator strings when the conductors are removed from the sag block to compensate for most of any error. However, where the slope of the line is excessive for any considerable distance, more exact methods must be used. An accurate method is to tension the section in question in such a manner that the unstressed length of conductor in the entire section is correct, although no individual span may be at design sag. The individual spans are then corrected by adjusting the insulator strings when the sag blocks are removed. For another solution, see reference 14.

In the following discussion it will be assumed that the sag blocks are frictionless, and that the sagger will regulate his subsequent sag procedure to produce this effect. With frictionless sag blocks the condition during tensioning is as shown in Fig. 20. After the conductor is transferred to the insulators, the parameter for all spans is to be constant at C_0, the design value. The two conditions are related by the fact that the unstressed length of conductor in the section is the same for both conditions. Let a be the change in unstressed conductor length per unit change in the value of C, and assume this rate constant within the range required. Then

$$(C_0-C_1)a_1+(C_0-C_2)a_2+(C_0-C_3)a_3+(C_0-C_4)a_4=0$$

$$(C_0-C_1)a_1+(C_0-C_1-d_1)a_2+(C_0-C_1-d_1-d_2)a_3+(C_0-C_1-d_1-d_2-d_3)a_4=0$$

Let

$$d_1=\Delta C_2,\ d_1+d_2=\Delta C_3,\ d_1+d_2+d_3=\Delta C_4$$

$$C_1=C_0-\frac{\Sigma(a\Delta C)}{\Sigma a}$$

$C_2=C_1+d_1$, etc.

The values of d are found approximately by scaling the profile while the values of a are best found from a chart made for that purpose. See Fig. 21.

The amount that the insulators at support B are to be offset from a vertical line drawn through that support is $(C_0-C_1)a_1$, while the similar offset at support C is $(C_0-C_1)a_1+(C_0-C_2)a_2$, etc. If the sense of d is taken as positive when the apex of span BC is above that of span AB and negative otherwise, the positive values indicate offsets to the right and negative values to the left of the vertical through the support.

Field procedure is to sag the section to the values C_1, C_2, etc. Frictional effect of the sag blocks is eliminated during the tensioning sequence. After

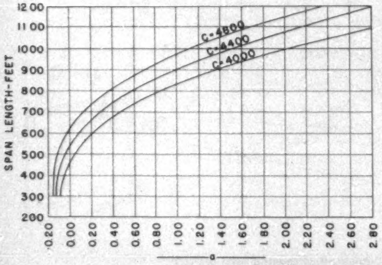

Fig. 21 (left). a versus span length for 605,000-CM ACSR 30 × 19, where

$$a=\Delta_1-\Delta_2$$

$$\Delta_1=\frac{L^3}{24C^2}-\frac{wCL}{AE}$$

$$\Delta_2=\frac{L^3}{24(C-100)^2}-\frac{w(C-100)L}{AE}$$

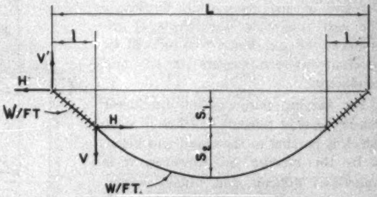

Fig. 22. Typical dead-end span

the sagging operations are completed and before the conductor is transferred from sag block to insulator at any support, the proper insulator position is marked at all supports. It should be noted that great precision in the calculations or marking is not required as small inequalities in tension will be equalized by small movements, from theoretical vertical, of the suspension insulator strings.

As an example of this process, in Fig. 20 let span $AB=800$, $BC=700$, $CD=600$, $DE=800$, and let $d_1=50$, $d_2=100$, $d_3=50$, and $C_0=4{,}400$. Then $\Delta C_1=0$, $\Delta C_2=50$, $\Delta C_3=150$, $\Delta C_4=200$, and from the curve of Fig. 21 $a_1=0.590$, $a_2=0.285$, $a_3=0.079$, and $a_4=0.590$. Also $a_1\Delta C_1=0$, $a_2\Delta C_2=14.25$, $a_3\Delta C_3=11.85$, $a_4\Delta C_4=118.00$; $\Sigma a=1.544$, $\Sigma a\Delta C=144.10$; and

$$C_1=4{,}400-\frac{144.10}{1.544}=4{,}307$$

It then follows that $C_1=4{,}307$, $C_2=4{,}357$, $C_3=4{,}457$, $C_4=4{,}507$; $a_1(C_0-C_1)=0.55$, $a_2(C_0-C_2)=0.12$, $a_3(C_0-C_3)=-0.04$, $a_4(C_0-C_4)=-0.63$; and the offset to the right at support $B=0.55$, at $C=0.55+0.12=0.67$, and at $D=0.67-0.04=0.63$.

Sag Adjustments After Installation

Occasionally the sag in a span must be adjusted after installation has been completed. This adjustment can readily be made by calculating the difference in the unstressed length of wire in the span at S_1 and S_2. The unstressed length of wire in a span is

$$=L\left(1+\frac{2.67S^2}{L^2}\right)-\frac{wL^3}{8MS}$$

where

w = weight of conductor, pounds per foot
M = modulus of conductor, pounds

Therefore, the amount of wire to be "cut in" or "cut out" of the span for change of sag from S_1 to S_2 is

$$l_1-l_2=\frac{2.67}{L}(S_1+S_2)(S_1-S_2)+\frac{wL^3}{8M}\left(\frac{1}{S_2}-\frac{1}{S_1}\right) \qquad (18)$$

or in terms of C

$$l_1-l_2=\frac{L^3}{24}\left(\frac{1}{C_1}+\frac{1}{C_2}\right)\left(\frac{1}{C_1}-\frac{1}{C_2}\right)+\frac{Lw}{M}(C_2-C_1) \qquad (19)$$

Sag in Dead-End Spans

In short dead-end spans, with low tensions, the effect of the weight of the dead-end insulator strings will be appreciable. In spans where this condition exists, such as rack spans at substations, clearances are generally kept to a minimum and the effect of the insulator strings should be accounted for. An approximate solution follows, see Fig. 22, which has proved adequate for this condition.

Taking the summation of moments about the point of support and solving for S_1

$$S_1=\frac{wl}{2H}(L-2l)+\frac{Wl^2}{2H}$$

and since $H=wC$, it then follows that

$$S_1+S_2=\frac{l}{2C}(L-2l)+\frac{(L-2l)^2}{8C}+\frac{Wl^2}{wC} \qquad (20)$$

Conclusion

The design of transmission-line tensions by precise but time-consuming methods is justified in unusual cases, but approximate and faster methods may be used to solve the problems encountered in the great majority of lines. However, these approximate methods are to be used with caution and only with a thorough knowledge of their limitations. Like a mechanic, the designer selects the tools that will most quickly produce satisfactory results.

◆

Discussion

L. T. Guess (Aluminum Company of America, Pittsburgh, Pa): I note the authors use the term "plastic flow" for the phenomenon described later in the paper as creep. I believe the term "creep" is in more common usage, especially among metallurgists, and in this case it is more specific. The definition of creep as used by metallurgists may be helpful to electrical engineers: "Creep is the flow or plastic deformation of material that occurs with time under load, after the initial deformation resulting from the application of load." Two references pertinent to the subject of creep are listed.[1,2]

H. H. Rodee (Aluminum Company of America, Pittsburgh, Pa.): This paper deals in a very practical manner with conductor sags and tensions and various associated problems. It should be of considerable interest to engineers concerned with the design and construction of transmission lines and a valuable contribution to the literature.

One of the subjects discussed in considerable detail is plastic flow or inelastic extension and its effect on sags and clearances. Of the three methods mentioned for stringing conductors to provide for this, the third is probably in most general use as the field operations will usually be less costly and less hazardous. The authors have stated that when this method is used the initial tension will frequently be higher than the maximum design tension. This statement, I believe, should be qualified to apply only to light loading conditions. I doubt that it would be true when the maximum design tension is based on heavy loading.

The inelastic extension that takes place following the installation of a conductor at initial tension without prestressing may develop gradually as a result of creep without any significant increase in loading, or it may occur quite rapidly as a result of loading with ice, snow, or wind. The customary procedure in computing sags and tensions is to provide for the inelastic extension and resulting increase in sag that will be produced by the maximum design loading. Under some conditions however, the inelastic extension or creep that develops gradually over a long period of time may result in a larger increase in sag than will be produced by the maximum design loading. Unless provision is made for this in the design, reduced ground clearance will result.

Creep is a function of stress and also a function of time. The rate of creep increases as the stress is increased, but it decreases quite rapidly with time. When plotted to a log-log scale the creep versus time relation is substantially a straight line; because of this characteristic, it is possible to determine with a high degree of accuracy the creep for long periods of time from tests extending over a few months.

As creep progresses in a conductor on a transmission line, the tension will decrease which, in turn, will cause the rate of creep to decrease. Creep is therefore to some extent self-stopping. The length of span will have considerable influence on this self-stopping action since the same unit creep will cause a larger reduction in tension in a short span than in a long span. Other conditions being equal, creep will therefore have a much greater effect on sags in long spans than in short spans.

Our laboratory has performed a considerable number of creep tests, some continuing for several years, on various sizes and types of conductors. The results show that the inelastic extension resulting from creep at normal tensions over the probable life of a transmission line will not exceed that resulting from the maximum design loading when the design is based on heavy loading conditions.

In light loading districts normal tensions are usually higher and spans longer, both of which will increase the effect of creep. On the other hand, maximum design tensions are usually lower than in heavy loading districts and the inelastic extension resulting from maximum design loading will be less. Creep will therefore usually be the predominating influence in light loading districts and should be taken into consideration in the design.

Under medium loading conditions, either the gradual creep at normal tensions or inelastic extension at maximum loading may be the predominating influence, depending upon size and type of conductor, span length and tension. For most conditions the differences will be small, and the customary practice of providing for the increase in sag after maximum design loading should be satisfactory. I believe that experience has generally confirmed this. Typical examples are given in Table III for a conductor size of 336,400-CM ACSR 30/7 and a span length of 1,200 feet. For purposes of comparison, the initial sag at 60 F was assumed the same as in both examples. The initial sags and the final sags after maximum design loading were computed by the method de-

Tension, pounds	3,180	3,550
Sag at 60 F after 10 years due to creep, feet	29.1	29.1
Tension, pounds	3,275	3,275

scribed in reference 6 of the paper, with no consideration being given to creep. Ten years was chosen arbitrarily as the elapsed time for determining the increase in sag due to creep since any further increase should be very minor because of the reduction in tension and the natural decrease in rate of creep with elapse of time. Also, it was assumed that during this time there was no increase in loading.

Paul F. Winkelman (Bonneville Power Administration, Portland, Oreg.): Some of the approximations where precise methods are not required in sag tension calculations are quite similar to our methods. However, to allow for creep and inelastic stretch, our sagging charts are based on virtual initial modulus of elasticity, whereas our maximum design templets for locating towers on the line profile are based on the final modulus of elasticity of the conductor. This virtual initial modulus curve goes through points of total elongation occurring during hold periods while increasing loads for the repeated stress-strain tests. Loads are successively held at 30, 40, 50, and 70 per cent of the conductor rated strength for periods of 1/2, 1, 3, and 3 hours respectively. In other words, this virtual initial modulus curve effectively allows for all the stretch occurring during these hold periods when used in determining stringing sags.

To duplicate the conductor elongation represented by this curve during sagging operations in the field, the sagger is required to hold the conductor 10 per cent above stringing tension for a minimum time of 15 minutes. This elongates the conductor the same amount as indicated by the virtual initial modulus for stringing tensions and removes sufficient creep to stabilize the conductor for field sagging. Furthermore, it provides for the permanent conductor set or inelastic stretch that occurs during initial maximum design loading. It also provides for a liberal amount of the additional creep that can be expected in that the final modulus of elasticity return curve is effectively offset by the creep occurring during test hold period at maximum design tension. A check of our repeated stress-strain curves indicates that this removes the amount of creep indicated by the 1,000-hour sustained load curve of Fig. 14 for 5,000 pounds or 18 per cent of rated strength which approximates our stringing tension. As the conductor will be stressed by loadings in the order of maximum design tension for only relatively short periods, the creep will be primarily controlled by bare conductor tension. These tensions would be considerably lower than the maximum design tension, particularly in heavy loading districts.

To prevent excessive errors in field sagging when the transit line of sight is tangent to the catenary too far from the point of true sag, we prepared a nomograph, Fig. 23, and a sample calculation, Fig. 24. The relation in conductor sagging error versus control factor is shown in Fig. 25. The sagging errors shown by these curves were determined by precise methods of sag calculations. By means of this control factor nomograph, the sagger can check in a moment the adequacy of his transit setup as this control factor is determined by data already available to the sagger.

In the short slack spans commonly used in substations, we determine insulator sag with the insulators installed on either one or both ends of the span for the convenience of the sagger. We determine insulator sag by a rather convenient method.[1]

W. C. Freeman (Sargent and Lundy Engineers, Chicago, Ill.): The authors have presented a comprehensive paper on transmission-line problems as a result of extensive experience.

My comments concern the section on "Sag in Dead-End Spans." The paper is not clear as to how the authors intend to use the data presented. If l is taken to be the projected length of the insulator assembly, how is this projected length obtained? If l is taken to be the actual length of the insulator assembly, which is the normally accepted method of calculating insulator deflections and conductor sags for short spans, the insulator string acts as a rigid body and the conductor span is considered to be constant and equal to the distance between supports minus the sum of the two string lengths.

We have had to calculate the sag carefully in connection with substation spans and have found this method can lead to appreciable error. It is apparent that the conductor span is L-2l only if the insulators are horizontal (l being the length of the insulator string). If the insulators deflect downward the length of the conductor span increases. This affects the sag and the tension. The tension increases and tends to pull the insulator string back to its original position. The solution is only possible by a step-by-step process but in many cases is well worth while. Table IV shows the difference in a typical case.

E. M. Wright (Pacific Gas and Electric Company, San Francisco, Calif.): The paper is most interesting, extremely well written, and well founded technically. The section on "Errors Beyond Control of Designer" is very good and should be considered at the time of design—even to the extent of the method and type of equipment to be used. With all this in mind, the designer is in a position to turn out a good practical design, based on calculations well within required tolerances.

The paper being on practical applications, we feel the method of computing sag, which is the correction from parabola to catenary, is not required in general. We only correct for this when the clearances are critical, or when extremely long spans are involved, as in the example used in the paper. However, when this is applied to a series of inclined spans we agree this should be done.

We handle the problem of side swing a little differently. We use a general series of clearance reduction factors, based on percent ground slope, to determine the reduction of ground clearance due to side swing. For horizontal displacement due to side swing, we computed stagger limitations based on the type of conductor, type or series of towers, and transmission-line separation. The stagger limitations are easy to compute and they eliminate all addition and subtraction when locating structures on profile. Determining clearance to towers by the use of a model seems a little cumbersome. We have worked out a rather complicated set of curves to be used with the profiles of the line to determine this clearance. A separate set of curves for each type of conductor and tower type is required. Although it takes a considerable amount of time to draw them, once they are made, and with trained personnel to use them, they are very practical as we often use the same conductor and series of towers on other lines.

The section on "Equivalent Span" is good; in fact we prefer this more theoretical ruling span to the empirical one. Although it takes longer to determine, it gives a more realistic approach.

The section on "Plastic Flow" is one of the best we have seen on this particular subject. We have felt for a long time that we should consider a longer creep period for all-aluminum and ACSR conductors. In general we use the first method described in the paper, and for the reasons outlined in the paper. We agree that the third method suggested would eliminate the necessity of increasing the creep period over the standard creep period in use today.

The remainder of the paper is very complete; however, we feel the method used to determine the offsets for suspension insulator strings in a series of inclined spans could be reduced to field work. The methods mentioned in the paper involve considerable design work for each tower involved, and they have to be based on assumptions as to field conditions at the time of stringing the conductor. We believe a more practical solution, especially as the paper deals with practical applications, would be to determine the clamping point in the field, after the conductor is strung to correct sag. A tool for this purpose has been developed in New Zealand.[1]

REFERENCE

1. TRANSMISSION LINE CONSTRUCTION PROBLEM. **E. B. Mackenzie.** *New Zealand Engineering*, Wellington, New Zealand, vol. 8, no. 10, Oct. 15, 1953, p. 354. Abstracted in *Water Power*, London, England, vol. 6, no. 9, Sept. 1954, pp. 358–59.

Maurice Landau (Department of Water and Power, Los Angeles, Calif.): Mr. Lummis and Mr. Fischer have presented an excellent summary of the practical application of sag and tension calculations to overhead power transmission lines. The authors demonstrate the necessity of using precise calculation methods and at the same time state the advisability of limiting the degree of accuracy of calculations to those obtainable on an ordinary slide rule. They point out the need for the exercise of judgment based on experience in applying the results of such calculations.

We have used ruling span curves similar to Fig. 9 for a number of years and have found them very satisfactory. The curves of Fig. 9 are for level spans. For transmission lines with large differences in elevation of supports we have found it advisable to prepare additional ruling span curves for spans with differences of elevation of 100, 200, 300 feet, etc. The calculations for these ruling span curves are made using the incremental method for sag tension calculations.[1,2] Use of this series of ruling span curves eliminates the necessity of special calculations for spans with large differences of elevation of supports.

The value of C for any section of the line is determined in a manner similar to that outlined in the present paper, the difference being that the ruling D (difference in elevation) is taken into account as well as the equivalent or ruling span. We have found the following approximate equation adequate for determining the ruling D

$$\text{Ruling } D = 1/2 \,(\text{average } D + \text{maximum } D)$$

1. INCREMENTAL METHOD FOR SAG-TENSION CALCULATIONS, **Maurice Landau.** *AIEE Transactions*, vol. 70, pt. II, 1951, pp. 1564–71.

2. *Discussion* by **Maurice Landau** of A SIMPLIFIED SAG-TENSION METHOD FOR STEEL-REINFORCED ALUMINUM CONDUCTORS, **C. A. Jordan.** *AIEE Transactions*, vol 71, pt. III, Dec. 1952, pp. 1117–18.

J. Lummis and **H. D. Fischer, Jr.:** We wish to thank the discussers for the interest they have shown. Mr. Guess' statement is well taken. We also prefer to use the word "creep" when referring to the phenomenon of flow or plastic deformation of material. The comments of Mr. Rodee and Mr. Winkelman regarding the effects of creep and their methods of handling this problem are very interesting and, while not differing to any great extent from those methods described in the paper, do provide valuable additional information on this topic.

Regarding Mr. Freeman's comments on the method presented for calculation of sag in short dead-end spans, l is taken here as being the actual length of the insulator string. This can cause an appreciable error where the tensions are very low, as is shown by his example. However, this error will be greatly reduced when tensions are 1,500 pounds or more.

The comments of Mr. Wright and Mr. Landau were of special interest to the authors, since they were based on experience gained from meeting problems similar to those existing on the Southern California Edison Company system. Undoubtedly the methods of sagging and determining clearances as described in these two discussions have been proved over a number of years and will therefore be investigated as to their application in our particular problems.

Each system has its own specific problems and construction standards that it maintains which are different from any found on other systems. For this reason certain methods of design and construction are more suited to one system than to another. In any case, the ultimate aim is an economical design of a transmission line. We hope that the paper and the discussions open up some new avenues to this objective.

Some Utility Ground-Relay Problems

H. C. BARNES
MEMBER AIEE

A. J. McCONNELL
MEMBER AIEE

THERE are many theoretical conditions which can result in false operation of ground relays. These conditions have not been of great concern since ample margin in either pickup or time has been available, especially if sequential tripping could be tolerated.

However, these margins are being diminished by the tremendous expansion of the utility system. The available ground-relay current is being reduced by the increased number of parallel lines, by heavier ground sources at each end of a line, by grounded primary transformers tapped solidly to lines, and by higher current-transformer ratics caused by higher line loadings. The time margin is disappearing because the added facilities make a more closely knit system with the result that faults affect much more of the system, making fast clearing more desirable. The recognized value of high-speed reclosing becomes even more important as the tapped loading increases, thereby precluding sequential tripping which would interfere with high-speed reclosing.

It is the purpose of this paper to point out some of the conditions that lead to false relay operation and to present oscillographic records in verification.

The causes of incorrect or undesired ground-relay operation can be classified in various ways, and are separated into two types: incorrect information supplied to the ground relay (false residual current), and correct information supplied to the ground relay, but with system conditions which cause the ground relay to make incorrect decisions (true residual current). Thus, "false residual current" is defined as a ground-relay current that has no system counterpart, and "true residual current" is defined as ground-relay current having a true system counterpart.

False Residual Current

False residual current can be the result of poor current-transformer performance, or can be caused by certain faults and load distribution even though the current transformers perform perfectly.

CURRENT-TRANSFORMER PERFORMANCE

False residual current attributable to current-transformer performance is the direct result of the variance of the current transformer ratio-correction factor from unity or some other constant and can be caused by unbalanced burden, by differences between individual phase current transformers, or by d-c saturation of the current transformers when the primary currents are offset.

Unbalanced Burden and Differences Between Individual Phase Current Transformers

Unbalanced phase burden as a cause of false residual current can easily be illustrated by the extreme example of the open-circuited current transformer of Fig. 1 during a phase-to-phase fault. Current flows in the ground relay, although the fault does not involve ground.

With all current-transformer circuits intact, and with balanced burden, ground-relay current can still flow as a result of differences in current-transformer characteristics even though there is no primary ground current. Although false residual-current difficulties from these causes are rather rare, the possibility nevertheless exists whenever high ground-relay sensitivity is used.

D-C Saturation of Current Transformers

While d-c saturation of current transformers caused by offset currents has received wide publicity in conjunction with bus-differential relays,[1-7] there has been little attention paid to a similar phenomenon resulting in unexpected transient residual current in ground relays during phase faults or during other overcurrent conditions not involving ground. The basic reason for false transient residual current is the unequal d-c saturation of current transformers caused by unequal d-c offsets of 3-phase currents, or unequal residual magnetism.[4]

Regarding 3-phase faults, fault current must be zero at the inception of the fault and, since the instantaneous values of the 3-phase fault currents cannot be the same in all three phases, the d-c offsets of the three phases cannot be identical. For example, if a 3-phase fault occurs at the time of maximum offset of one phase, the current transformer in that phase will probably become d-c saturated causing its secondary current to be deficient. The other two current transformers being subjected to only half of the maximum d-c offset may not saturate at all; or if they saturate, they will do so later and less severely. The net result is a false residual current in the ground relay.

Similarly, unequal residual magnetism resulting from previous current-transformer history can cause false residual current. Without residual magnetism and with identical current-transformer characteristics, there should be no false residual current during a phase-to-phase fault, regardless of primary-current offset. Any deficiency in the output of one current transformer would be exactly balanced by the deficiency of the output of the second current transformer. However, unbalanced residual magnetism can cause d-c saturation of one current transformer and, to a lesser degree, of the second current transformer. Again, the net result is a false residual current in the ground relay.

Since this phenomenon is of a transient nature, the performance of high-speed relays is of principal concern. Slow-speed relays are seldom affected, except possibly when there is a high d-c time constant. As an example, consider the line relaying of Fig. 2 in which an instantaneous-ground-overcurrent relay is used to improve ground-fault protection. It is assumed that limitation of ground-fault current requires a high relay sensitivity relative to that of the phase relays. For

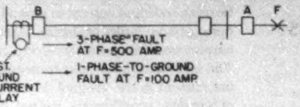
Hauspurg, American Gas and Electric Service Corporation, for his assistance.



B
A
F
3-PHASE FAULT AT F=500 AMP
1-PHASE-TO-GROUND FAULT AT F=100 AMP
INST. GROUND OVERCURRENT RELAY

Fig. 2. Sensitive instantaneous ground relay used to improve ground-fault protection

the single-phase-to-ground fault magnitude of 100 amperes at F near bus A, a reasonable ground-relay setting might be 120 amperes. A 500-ampere 3-phase fault at F should theoretically cause no current to flow in the ground relay at B. However, d-c saturation of current transformers may easily cause a ground-relay current in excess of its pickup, thus causing an incorrect tripout. Overreach because of this can be prevented by increasing the ground-relay pickup or by introducing a short time delay in the ground-relay trip circuit, each of which sacrifices some protection. Also, false residual current can be reduced by inserting resistance in series with the ground relay.[8] This method requires considerable application-engineering effort and is not necessarily a complete solution. A sure solution, but seldom feasible, is to operate the ground relay from a current transformer with a magnetic circuit which surrounds all three phase currents.[9]

Although the published information on this subject indicates that the problem is very complex, the following simple equation can be used to indicate whether or not trouble can be expected

$$B_{\max}=\frac{\sqrt{2}\,10^8 ITRN_1}{A(N_2)^2} \qquad (1)$$

where

$B_{\max}$ = maximum flux density in lines per square inch
I = symmetrical primary short-circuit current, amperes rms
T = d-c time constant of primary current, seconds
R = resistance of secondary circuit of current transformer and phase relays, ohms (not including ground relay)
N_1 = primary turns of current transformer (=1 for bushing current transformer)
A = core area of current transformer, square inches
N_2 = secondary turns of current transformer

The foregoing equation was derived on the basis of infinite permeability of the current-transformer iron. Spot analytical checks with the variable permeability of the usual current-transformer iron have indicated that the results using infinite permeability are pessimistic to a minor degree. Practically, the residual flux further limits output and, therefore, the results from this method are optimistic.

With the iron used in current transformers, saturation usually occurs at flux densities over 100,000 lines per square inch, though appreciable error probably occurs only above 125,000 lines per square inch. In the example of Fig. 2, the following values are assumed:

I = 500 amperes
T = 0.01 second
R = 1 ohm
N_1 = 1
A = 4 square inches
N_2 = 20

$$B_{\max}=\frac{\sqrt{2}\,10^8\times500\times0.01\times1\times1}{4(20)^2}=$$
442,000 lines per square inch

Since 442,000 lines per square inch is large compared to 125,000, ground-relay difficulty can be anticipated.

Fig. 3 is an oscillogram of a staged, bolted, 3-phase fault (not involving ground) which was made to test an oil circuit breaker. Trace 3 shows the false residual current in the ground relays of one of the lines. Only a slight amount of true residual current appeared in the transformer neutral (trace 2).

D-C Saturation During Synchronizing

Closing out of synchronism can result in 3-phase currents comparable with short-circuit currents. Accordingly, transient residual current can appear in the ground relay because of d-c saturation of current transformers. Fig. 4 shows false residual currents appearing when a steam turbine generator was reclosed about 60 degrees out of phase with the system. In the upper oscillogram of Fig. 4, the second trace from the bottom shows residual current at one line terminal. In the lower oscillogram of Fig. 4, the second trace from the bottom shows residual current at the opposite line terminal. Both of these traces show considerable residual 60-cycle currents (false residual current) unexpected because of

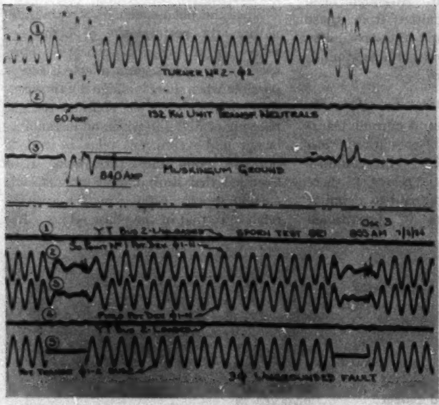


Fig. 3. Example of false residual current during a 3-phase fault

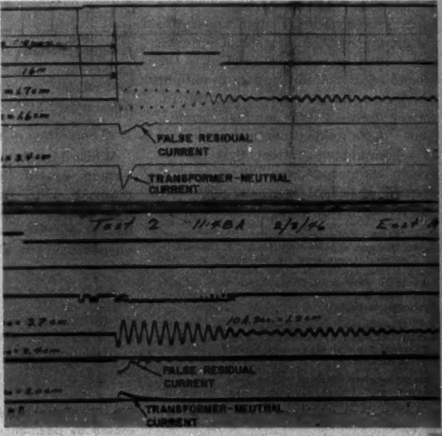

Fig. 4. Examples of false residual current during reclosing

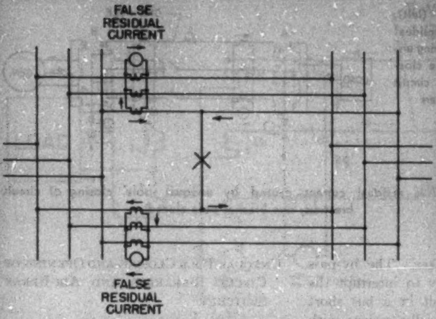

Fig. 5. False residual current during a fault involving two different phases of parallel lines

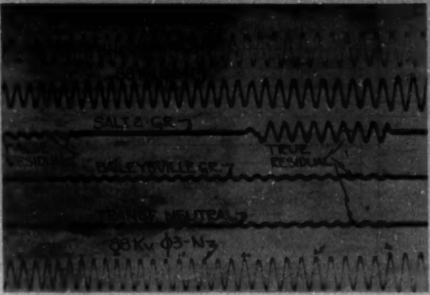

Fig. 6. Example of false residual current during a 3-phase fault involving two phases of one line and the third phase of a parallel line

the balanced 3-phase conditions. The bottom traces of Fig. 4 (transformer-neutral current) confirm that there is a negligible true 60-cycle current in each transformer neutral and, therefore, there should be a negligible true 60-cycle residual current. Inspection of Fig. 4 will show that the false residual currents at opposite ends of the line differed considerably. This can probably be explained on the basis of different residual fluxes (previous currents having been internal-fault currents), though even presumably identical current transformers sometimes differ considerably because of differences in iron characteristics.

Although the phase-comparison relays did not trip incorrectly during the test of Fig. 4, a previous test resulted in an incorrect tripout. After the previous test, it was found that the zero-sequence sensitivity was much greater than necessary. By reducing the sensitivity, successful reclosing was obtained. However, had not the reduction of ground-fault sensitivity been permissible, other measures would have been required such as introduction of time delay to the ground relays during closing.

MULTICIRCUIT FAULTS

False residual current resulting from system faults during normal system operation and not caused by poor current-transformer performance is the direct result of the inadequacy of the usual current-transformer connections to determine the actual ground current flowing. For example, Fig. 5 shows how false residual current can occur as a result of a fault between a phase of one line and a different phase of a parallel line, with ground not involved. Similarly, a 3-phase fault can result in false residual currents whether or not ground is involved.

Fig. 6 is an oscillogram of a 3-phase-to-ground fault as a result of different phases flashing over on the two circuits of a 132-kv double-circuit construction. Phase 1 on circuit no. 2 and phases 2 and 3 on circuit no. 1 flashed over during a lightning storm. It is not uncommon that different phases flash over on this type of construction, since phasing top-to-bottom is usually 1-2-3 on one circuit and 3-2-1 on the other to minimize system unbalance.

Circuit no. 2, on which only one phase was involved, tripped properly from carrier and high-speed reclosed successfully but, on circuit no. 1 having two phases involved, tripping was blocked until circuit no. 2 opened.

It can be seen from voltage trace 1 that phase 1-*N* (from potential on the 88-kv side of an autobank) was restored at 6 cycles when the Saltville circuit no. 2 (trace 3) opened. At this point, phase 2-*N* and 3-*N* voltages rose slightly but were not fully restored until the no. 1 circuit cleared at about 30 cycles. Circuit no. 1 was not connected to the oscillograph because of element limitations but clearing can be seen from the other traces. Note that very little current appeared in the bank neutral (trace 5) or the Baileysville circuit residual (trace 4) until circuit no. 2 opened at 6 cycles to change the fault from 3-phase to ground to 2-phase to ground. The residual current in circuit no. 2 (trace 3) can be seen during this period. Also, when this circuit reclosed successfully at 20 cycles, its contribution to the fault remaining on circuit no. 1 can be seen.

Analysis of the sequence components revealed that the torque to a carrier directional-ground relay on the double-faulted circuit no. 1 was in the nontrip direction. This carrier scheme utilized a separate carrier directional-ground relay which took preference over the 3-phase directional relay and, therefore, continued carrier blocking until circuit no. 2 opened. The time-delay reset of the blocking auxiliary relay further delayed tripping. A more modern scheme utilizing distance-type phase relaying would probably have operated properly since ground preference is not used and, also, since better first-zone coverage is realized.

The flow of false residual current, as shown in Figs. 5 or 6, might appear to be an advantage in that ground relays have an opportunity to operate as well as phase relays. However, there can be disadvantages such as the following:

1. Relay selectivity can be affected, resulting in a tripout of a circuit breaker or an unfaulted line.
2. Although the fault will be removed ultimately, sequential operation may result. Such operation may present the successful high-speed reclosing of both lines.

This general subject is too complicated to be dealt with in its entirety in this paper.

UNEQUAL POLE CLOSING AND OPENING OF CIRCUIT BREAKERS AND AIR-BREAK SWITCHES

Unequal pole closing of circuit breakers, a condition impossible to avoid, can cause false residual current (as well as true residual current which will be discussed later), as illustrated in Fig. 7 which shows one phase of one of two parallel lines still open. The system of Fig. 7 is shown ungrounded for easy understanding of this phenomenon. Similar false residual current can occur if the system is grounded.

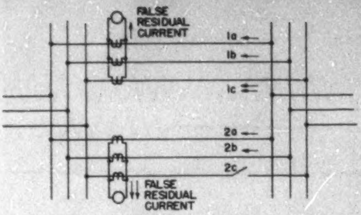

Fig. 7 (left). False residual current during unequal pole closing of circuit breakers

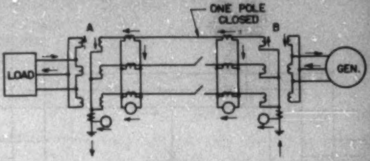

Fig. 9. True residual current caused by unequal pole closing of circuit breakers; one breaker pole closed

Fig. 8(A), while not an actual unequal-pole-closing operation, clearly illustrates the effect. This oscillogram is the result of one conductor of one of a pair of 132-kv circuits pulling apart in mid-span because of a splice failure. Trace 4 is the residual current of this line. When the conductor opened, and before it hit the ground, the false residual equivalent of phase current appeared even though there was no fault, as shown by the voltage traces 1, 3, and 6. This false residual current started carrier transmission to block tripping until the conductor hit the ground about 29 cycles later. The line relayed from backup caused by the time-delay dropout feature of the carrier-blocking auxiliary relay.

Fig. 8(B) trace 1, shows the false residual current caused by unequal pole opening and closing when switching load on a parallel line by means of a circuit breaker.

An exaggerated example of unequal pole closing or opening is when operating an air-break switch such as a line-sectionalizing switch. Also, when used as a by-pass switch, the air-break switch can be particularly dangerous, especially on opening. For example, when the first pole of the switch opens, false residual current may cause the ground relays to trip the circuit breaker. The by-pass switch would then try to interrupt the line current and result in a bus short circuit. This is especially serious with schemes cutting out bus differentials during by-pass conditions.

SYSTEM UNBALANCE

The previous example of an open phase, Fig. 7, is simply an extreme example of unbalanced phase impedance caused by lack of transposition of line conductors. False residual current can flow either during faults not involving ground or during normal load conditions. Fig. 8(B) also shows false residual current during normal load conditions (trace 1 before opening and after reclosing).

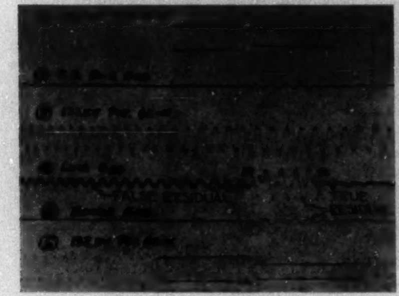
True Residual Current

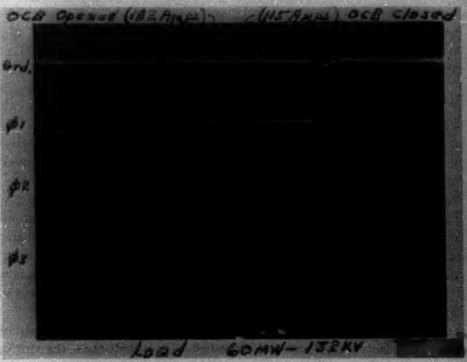
It is easy to understand how ground relays can be fooled when there is no actual ground current. However, it may not be so easily understood that ground relays can also be fooled by actual ground currents. Such actual ground currents can be caused by unequal pole closing, by normal system unbalance, by induction, or by magnetizing-current inrush into power transformers.

UNEQUAL POLE CLOSING AND OPENING OF CIRCUIT BREAKERS AND AIR-BREAK SWITCHES

Unequal pole closing can cause a flow of ground current in directional-ground relays that is impossible to distinguish from an internal ground fault on the basis of relative direction alone. This is illustrated in Fig. 9, which shows the circuit conditions with one breaker pole at station *B* closed. It is apparent that a directional-ground relay at *B* would believe that there is a line fault. Not so apparent is the fact that a line relay at *A* would also believe that there is a line fault, although the relaying conditions at the two line terminals are actually identical. The line current relative to the transformer-neutral current at terminal *A* is the same as at terminal *B*. Thus, both line relays "see" what appears to be a line fault, and a high-speed directionally-relayed line might trip. It makes no difference how the relays are polarized, since zero-sequence voltage and neutral current are proportional at the grounded transformer location. Fig. 10 shows a similar circulating ground current after the second circuit-breaker pole at station *B* has closed.

Fig. 8. Example of false residual current (A) (below) when one phase conductor opened; (B) (right) during unequal opening and closing of a circuit breaker





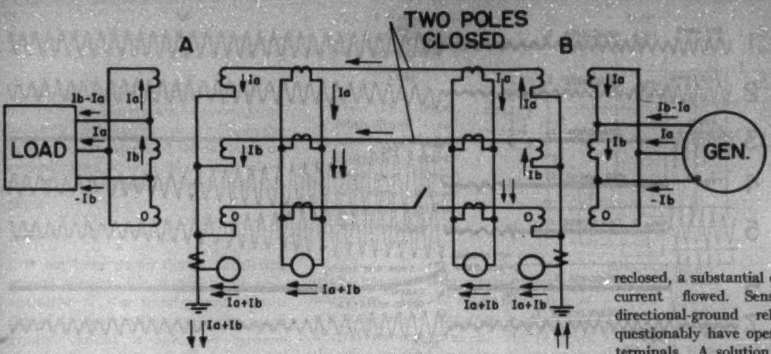


Fig. 10 (left). True residual current caused by unequal pole closing of circuit breakers, two breaker poles closed

Fig. 4 was used to illustrate the false residual current which was caused by d-c saturation of current transformers. It also illustrates the true residual and transformer-neutral current caused by unequal pole closing of circuit breakers. The two bottom traces of the oscillograms of Fig. 4 show transformer-neutral currents at opposite ends of a transmission line. When the second circuit breaker reclosed, a substantial circulating ground current flowed. Sensitive high-speed directional-ground relays would unquestionably have operated at both line terminals. A solution would have been the addition of a short time delay in the trip circuit during closing or reclosing.

Fig. 11 is an oscillogram taken to check transferred tripping. The system consisted of a 50-mile 330-kv line terminated in a 150-megavolt-ampere 330/132-kv autotransformer at each end and with breakers only on the 132-kv side. Where the circuit breaker at the local end opened, definite spikes can be seen in the transformer tertiary current and in the line ground-relay current traces as well as in the 132-kv bus zero-sequence potential. Also of interest are the high-frequency oscillations between the transformer inductance and the line capacitance as reflected in the tertiary and in the output of the potential devices on the 330-kv line where the remote circuit breaker opened.

These illustrations involve the closing or opening of load current and are particularly concerned with directional-ground-relay operation. Unequal pole closing can also cause operation of ground relays when energizing a line.

As would be expected, line-charging current enters the picture only on the longer lines. As as extreme example, consider energizing the long line of Fig. 12. Upon the closure of the first breaker pole at *A*, a ground current will flow which may be comparable with the ground

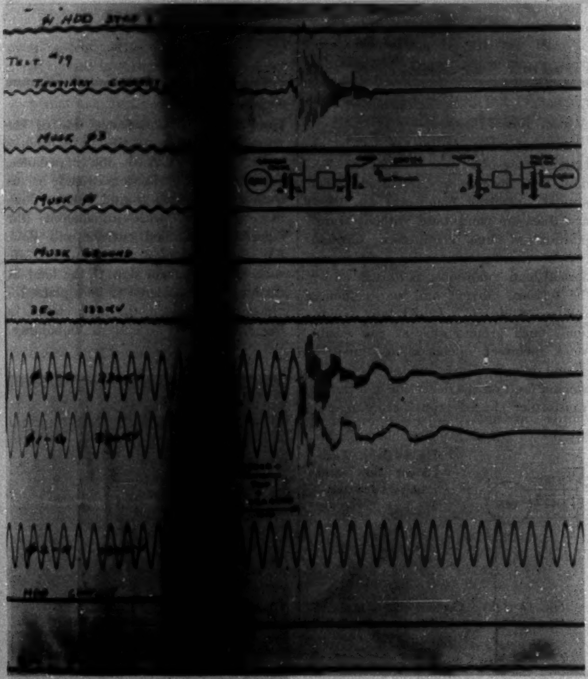

Fig. 11. Example of true residual current caused by unequal pole opening of circuit breakers

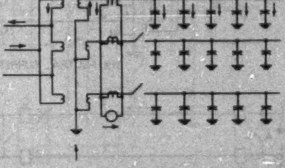

Fig. 12. Residual current when energizing a long line

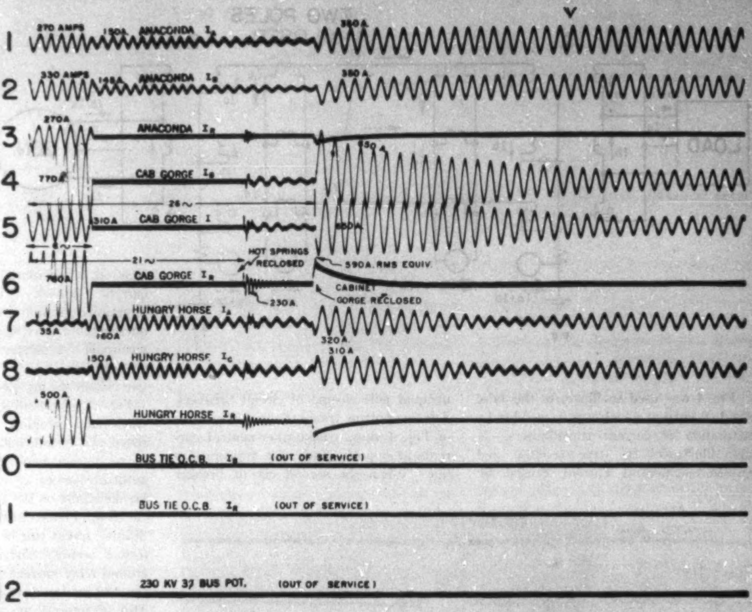

Fig. 13. Example of residual current when energizing a long line. Note high-frequency current, trace 6, when Hot Springs reclosed

current which can flow into a distant fault. More usual, however, is the ground current which flows as a result of the resonant combination of zero-sequence line capacity and the magnetizing inductance of the supply transformers.[10] Fig. 13, trace 6, illustrates such a line-energizing transient and shows that a considerable magnitude of high-frequency current is possible. In extreme cases, it has been necessary to filter out the nonfundamental-frequency currents to avoid undesired relay operation. Another solution would be the use of a harmonic-restrained relay as a fault detector.[11]

Normal System Unbalance

Unequal closing of breaker poles is an extreme case of system unbalance. Today, few systems are balanced under normal operating conditions as many new lines are being built without transposition of line conductors. Ground current can be substantial even under normal load conditions, as illustrated by the tertiary current and zero-sequence voltage of Fig. 11. Under fault conditions, such ground current can easily cause incorrect operation of sensitive ground relays. Cases are on record in which a fault on the delta side of a power transformer caused ground-relay operation on the grounded-wye side of the transformer. Fig. 14 illustrates such a fault. With balanced line impedance, the current distribution would be as indicated, with no ground current flowing. However, with unbalanced line impedances, ground current will flow. Fig. 9 can be used again to illustrate such ground-current flow if the load at station *A* is considered to be a phase-to-phase fault. Again, the open circuit in Fig. 9 represents an extreme unbalance.

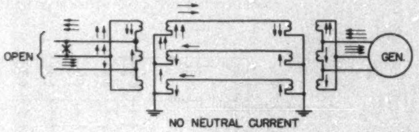

Fig. 14 (left). Fault-current flow with balanced system

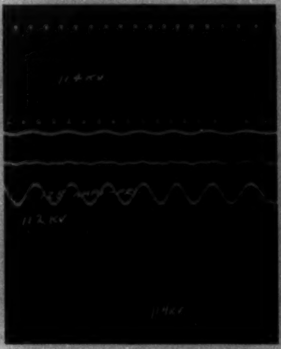

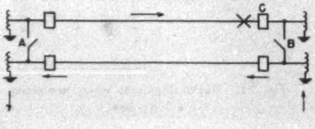

Fig. 15 (left). Ground current induced in a line by a ground fault on a parallel line

Fig. 16 (right). Example of 25-cycle current induced in a 60-cycle line

Fig. 17 (left). System conditions before energizing a transformer

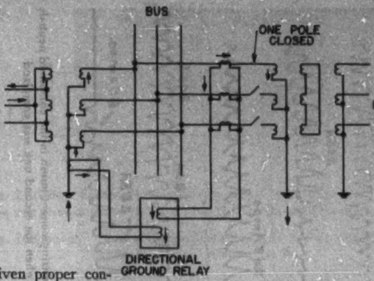

Fig. 19 (right). Magnetizing-current inrush when energizing a power-transformer integral with a line. Ground relay polarized from bus transformer neutral

Although ground current flows during normal system operation because of unbalanced line-charging current, calculations have indicated that the influence on ground relays is negligible compared to the other considerations described in this paper.

Induction

It has been shown that a circulating ground current, Fig. 9, can cause misoperation of directional-ground relays. One of the most usual causes of circulating ground current is induction between parallel lines. Fig. 15 illustrates such a case in which a ground fault on one line causes a circulating ground current in the parallel line. Oscillographic evidence of induced ground current is most convincing when the power system involves more than one frequency. Fig. 16 is an example of a 25-cycle fault inducing 25-cycle ground current in a 60-cycle system. The oscillograph was connected to observe only phenomena on the 60-cycle system. The appearance of a 25-cycle current is therefore conclusive.

Sometimes, relay sensitivities can be such that incorrect operation by induced current can be avoided. Other solutions of this problem have consisted of zero-phase-sequence overvoltage relays or phase-to-neutral-connected undervoltage relays arranged to monitor the normal ground relays. Pilot-wire or phase-comparison carrier relays eliminate the problem because they compare the currents entering and leaving the line, from whatever cause.

MAGNETIZING-CURRENT INRUSH

Energizing a Transformer

The effect of magnetizing-current inrush into power transformers on transformer-differential relays has long been known. However, its effect on ground relays has not been given proper consideration. Fig. 17 shows a portion of a system before energizing a grounded-neutral transformer at *A*. Fig. 18 shows the magnetizing-current inrush into transformer *A*, as well as the source of that current, transformer *B*. Here again is the now familiar circulating current which can cause directional-ground relays to operate incorrectly.

Little difficulty has been reported of line-relay tripouts when energizing a power transformer external to the line, although in one instance such a tripout could be definitely predicted and a harmonic-restrained relay was used to monitor the ground-relay trip circuit. A-c pilot-wire relaying or phase-comparison relaying should not be subject to incorrect operation from this cause.

If the transformer is integral with the line, i.e., no line-side circuit breaker, the relays at the energizing terminal may or may not operate unnecessarily, depending upon the location of the current transformers. For example, in Fig. 19 the direction of the residual current relative to the polarizing current is the same as for a single-phase-to-ground line fault. The directional-ground relay may therefore operate to retrip the circuit breaker. Incidentally, a-c pilot wire or phase-comparison relaying are also subject to false tripping if the protected zone includes a power transformer.

It is apparent that magnetizing-current inrush could not operate the directional-ground relay if residual current were obtained from current transformers in the high-tension bushings of the line power transformer. Even with this arrangement, false tripping can occur if the transformer is energized from the line. This could occur during high-speed reclosing where the remote circuit breaker closed slightly ahead of the local circuit breaker because of air pressure or temperature difference, etc. The local circuit breaker would then receive a trip impulse from the preclosed relay contacts when it closed. Also, undesired tripping can be avoided by polarizing the ground relay from current in the neutrals of the line power transformer, as shown in Fig. 20.

For proper operation during faults, the directional-ground relay of Fig. 20 may be polarized from the power-transformer delta. This is especially desirable if the power transformer is an autotransformer.[13] With delta-current polarizing, it would appear that there should be no magnetizing-inrush difficulty because little delta current would be expected, and any delta current which flows would be expected to be in the nontripping direction, as with the polarizing means of Fig. 20. However, magnetizing-inrush phenomena can be very complicated, and

Fig. 26 (above). Effect of charging current of unfaulted parallel line on directional-ground relay operation

delta-current polarizing cannot be depended upon to prevent undesired relay operation.

Fig. 21 is an oscillogram taken during the energizing of one of the 330/132-kv 150 megavolt-ampere autotransformers of Fig. 11 from the 132-kv side with the 330-kv line disconnects open. The carrier ground relays tripped. They were connected in the residual circuit of bushing current transformers in the 132-kv circuit breaker, trace 5, and were polarized from the tertiary, trace 2. Note that the residual current, trace 5, changed direction after 2 cycles, whereas the tertiary current, trace 2, did not.

The complication of magnetizing-current-inrush phenomena is further exemplified by Fig. 22 showing the combined neutral current of two power transformers when the second transformer was energized.[10] Ground backup overcurrent relays unnecessarily removed both power transformers from service. Fig. 22 is all the same trace cut into sections to show that magnetizing-current inrush can continue long enough to operate even long time relays.

Removal of a Fault

Although the results of magnetizing-current inrush when energizing a transformer have been common knowledge, the fact that removal of a nearby fault has a similar effect on a transformer[11] has been somewhat overlooked. The only difference is that removal of a fault at current zero results in less than maximum magnetizing-current inrush because the

voltage increase occurs at a more favorable angle.

The removal of a ground fault external to the protected line section can result in a magnetizing-current inrush similar to that illustrated in Fig. 18. The directional-ground relays are thereby subject to false operation. Modern directional-comparison carrier relaying utilizes a safeguard (sometimes called "transient blocking") which operates in the following manner: assume that line *A-B* of Fig. 18 is protected by directional-comparison carrier relaying. Upon the occurrence of a ground fault off the bus at station *A* and external to line *A-B*, a carrier-blocking signal is transmitted to terminal *B* to prevent tripping there. Shortly after the start of transmission of the blocking signal, an auxiliary relay operates to "seal in" the blocking signal. When the external fault is removed, the blocking signal continues for several cycles regardless of directional-relay operation and usually blankets the period during which magnetizing-current inrush might otherwise cause incorrect tripping of the line relays. In extreme cases, several cycles of transient blocking may not be sufficient, as indicated in Figs. 22 and 23.

Fig. 23 shows the magnetizing inrush following removal of a 3-phase bolted fault not involving ground. The inrush is reflected in all three phases, the bushing-current-transformer residual circuit common, and the tertiary. This condition continued with diminishing values far in excess of 2 seconds.

Fault Incidence

Previous to Fig. 24, the authors know of no record of a fault causing magnetizing-current inrush. This was a circuit-breaker failure at a generating station. At the beginning of Fig. 24, the oscillograph was still running from the original fault when the fault recurred as a phase-to-phase fault, as shown at *A* on the voltage trace 1. The characteristic magnetizing current is shown in line residual trace 3.

Also of interest is the fact that magnetizing-current inrush can occur when a fault changes character. At point *B* of Fig. 24, a further magnetizing-current inrush occurred when the phase-to-phase fault involved the third phase. The mechanism by which a magnetizing-current inrush can occur on the incidence of a fault may be of interest and is illustrated in Fig. 25.

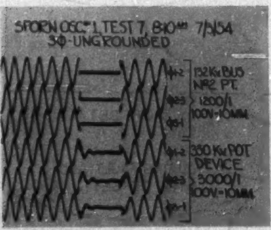

Fig. 27. Potential-transformer and potential-device responses during a 3-phase fault not involving ground

LINE-CHARGING CURRENT WITH PARALLEL LINES

Another manifestation of the effect of zero-sequence line-charging current appears in parallel lines. Fig. 26 shows the zero-sequence network with a fault near the middle of one line. If charging current is neglected, a fault location can be found which results in substantially no current in the unfaulted line. However, with line capacity considered, current will flow in the unfaulted line, as shown in Fig. 26. Comparison of the currents in the faulted and unfaulted lines would seem to indicate that, if relays were connected to trip the faulted line, similarly connected relays on the unfaulted line would not trip. However, the currents in the nonfaulted line are charging currents, whereas the currents in the faulted line are largely inductive. Hence, although the currents in the unfaulted line appear to be in the nontripping direction, they are actually in the tripping direction. The only solution of this problem appears to be based on current magnitude, which, in turn, appears to indicate that no solution is available if the charging current, under the conditions of Fig. 26, is comparable with the minimum ground-fault current for which tripping is required. A possible solution would be reduced sensitivity plus 2-way transfer tripping.

Combinations of False Residual Current and True Neutral Current

The directional-ground relay appears to be the only type that can be influenced by combinations of false residual current and true neutral current. In general, incorrect relay operation can occur if there is false residual current from any cause, e.g., Fig. 3, trace 3, simultaneously with transformer-neutral current from any cause e.g., Fig. 3, trace 2.

Particularly prone to misoperation is the directional-ground relay when used on a resistance-grounded, or other poorly grounded, system. Such a system requires high ground-relay sensitivity. Tripping can result from an external 2-phase-to-ground fault which provides adequate neutral-polarizing current and a heavy phase-to-phase component to produce false residual operating current. A potential-polarized directional-ground relay would be exposed to the same chance of misoperation.

Combinations of False Residual Current and False Residual Voltage

Again, the directional-ground relay is involved because of the two quantities required for misoperation. In general, incorrect relay operation can occur if there is false residual current from any cause, e.g., Fig. 3, trace 3, and false residual voltage caused by the imperfect performance of potential transformers or devices during faults not involving ground.

The authors have no examples of false residual voltage resulting from imperfect performance of potential transformers. The top three sinusoidal traces of Fig. 27 show the responses of potential transformers during a 3-phase fault not involving ground. The clean-cut reduction of secondary voltage to zero indicates that any false residual voltage would be negligible. On the other hand, the bottom three traces of Fig. 27 show the responses of potential devices. Fig. 28, trace 3, shows the false residual voltage resulting from the summation of the three potential-device voltages of Fig. 27.

Other Reasons for Ground-Relay Misoperation

It is recognized that there are other reasons, not covered in detail in the foregoing, for ground-relay misoperation. Such reasons have not been discussed

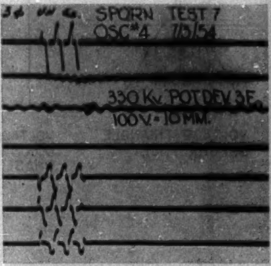

Fig. 28. Example of false residual voltage of potential devices during the 3-phase fault of Fig. 27

because they have already been described in the literature. These include at least the following.

1. Effect of steady-state current transformer exciting current on ground-relay sensitivity.[14]

2. Effect of unbalanced phase-to-neutral loading of distribution transformers on ground relays.[15]

3. Other problems involving polarizations of ground relays.[12]

4. "Neutral inversion" of potential transformers.[16, 17]

5. Another incorrect response of potential devices.[18]

Summary

The foregoing causes of incorrect or undesired ground-relay operation are summarized in Tables I and II, Table I for false residual current and Table II for true residual current. Included in the tables are the relay types affected, the kind of incorrect operation which might be expected, and the possible remedial measures.

Conclusions

1. The number of true and false residual currents and their combinations which can adversely affect ground relaying are many.

2. Unnecessary ground-relay sensitivity should be avoided. If a 2-ampere ground-relay pickup is sufficient, a lower one may not be better but rather may invite trouble.

3. In planning system expansion, ground relaying must be given careful consideration to avoid conditions where adequate ground relaying is virtually impossible.

4. If system expansion continues to demand further increases in ground-relay speed and sensitivity, it can be expected that false tripping by ground relaying will increase.

5. It may be necessary to change some operating practices. Some helpful items would be:

a. Reduction in the number of transformers operating with their neutrals grounded at a terminal to permit more uniform fault current distribution. Even this gain may not be too great since the positive- and negative-sequence components will remain. The problems of overvoltage and cost of providing insulation for ungrounded neutral operation will also limit this practice.

b. More extensive use of high-speed reclosing to minimize the effect of false tripping.

c. Increased use of devices to prevent flashover (counterpoise, static wires, etc.)

to reduce the number of occasions for false operation. An additional justification of this would be reduction of danger of equipment failure from the increasing fault-current magnitudes.

d. More extensive application of a-c pilot wire or phase-comparison carrier each of which is generally immune to the ground-relaying difficulties occasioned by the system itself. However, even these are subject to incorrect operation from false current-transformer output. Their use is also complicated by the multiple-tapped line.

Discussion

M. Stephens Merritt (Tennessee Valley Authority, Chattanooga, Tenn.): The authors are to be commended for information on undesirable relay operations which are exceedingly difficult to isolate and eliminate. In most cases where such unwanted operations occur, such action accompanies other phenomena which, without the benefit of automatic oscillograph records of the necessary quantities, cannot be isolated as to their cause. This, among other things, points up the need for much more oscillographic equipment than is available on most power systems. It is necessary that the oscillograph operation be initiated from a very sensitive ground-relay element.

It is probable that all of these phenomena have been experienced on substantially all large electrical utility systems at one time or another even though they may not have been recognized. Except for the potential inversion listed as no. 4 in the section entitled "Other Reasons for Ground-Relay Misoperation" and the combination of false residual and true neutral current, they have all been recognized on the Tennessee Valley Authority system. Some of these spurious relay operations have been desirable, e.g.: a grounded-wye/delta stepdown transformer on the end of a short high-voltage line supplying a large industrial load developed a turn-to-turn fault in the low-voltage delta winding of one phase. The circuit was protected by means of pilot-wire relaying from the source station to the load side of the stepdown transformer for phase faults and to stepdown transformer neutral for ground faults. The unbalanced current in the phase conductor and neutral circuits as a result of the load or fault caused the pilot-wire ground relays to open the supply oil circuit breaker.

The desirable tripping results have been very few, but the highly undesirable tripping results have been many. This is especially true for the primary transmission system where most of the lines are protected by terminal comparison-carrier relay. The conditions producing these effects in most cases probably would not have been recognized except for the availability of automatic oscillographs. The recognizance of the causes has permitted some remedial measures to be taken. These measures involve:

1. Engineering design of system and stations to minimize system arrangement and operations favorable to these spurious operations.
2. Control of switching operation, especially where operation of air-break switches is involved to minimize conditions favorable to undersirable tripping on unbalanced loading or lack of simultaneous pole operations.
3. Closer adjustment of oil circuit-breaker poles in clearances than the tolerances given by manufacturer's instructions.
4. Calibrating relays available to minimum sensitivity commensurate with acceptable ground fault recognition.
5. Closer attention to application of protective relay schemes.
6. Improved characteristics effected by the manufacturers of protective relay schemes.

There yet remains much trouble on the primary transmission system from unsymmetrical oil circuit-breaker pole operation and changes in magnetization. It has not been possible in many cases to separate these phenomena since the unsymmetrical breaker pole operation is present when a tie line is closed, either automatically or when synchronizing, transformers are energized, and a fault is removed.

The methods employed by manufacturers for improvement of the relays for these conditions have been limited to substitution of high-speed induction ground-relay elements for those operating on the solenoid principle and installing in the relay coil circuits some means of energy absorption to prevent operation on short-time low-magnitude transients. The high-speed induction elements have proved effective in overriding these short-time transients with the sacrifice of about 3 cycles on low-magnitude ground faults and about 1 cycle on high-magnitude ground faults. This sacrifice in time is preferable to the unwanted operations.

The results obtained with the present relaying equipment are not satisfactory. Dissatisfaction results from continuing to get unwanted tripping where the slightly slower induction relay is not used and having greater clearing time for ground faults than should be necessary. The paper does not extend much hope of improvement without adding considerable complication by way of additional relay elements. Superpositioning of phase comparison on terminal comparison-carrier ground relaying is now being installed in a few severe cases of induction or mutual coupling but cannot feasibly be considered for general installation to remedy other difficulties. The field is still open for the manufacturers to arrive at some solution which with minor modifications to existing installations will eliminate the present deficiencies.

A high percentage of failures of high-speed automatic reclosing of oil circuit breakers on the primary transmission system has been experienced in the past. It may be that some of these which were ascribed to failure to latch, multiple lightning discharges, etc., may have been caused by the unsymmetrical circuit-breaker pole operation or transformer magnetization.

G. D. Rockefeller and **J. L. Blackburn** (Westinghouse Electric Corporation, Newark, N. J.): This paper is a valuable contribution in cataloguing the various troubles occasionally encountered in ground relaying and will be helpful to relay engineers in tracing these troubles. It should be noted that, generally speaking, these troubles occur relatively infrequently considering the large number of ground relays in successful service. This is pointed out by the authors, but merits re-emphasis lest some become unduly concerned after reading the paper.

Negative-sequence quantities are used very effectively in ground relaying to solve the difficult problem of induction. It is regretted that this was not mentioned in the paper. The amount of negative sequence induced even with untransposed lines is very small and generally negligible.[1] Thus, negative-sequence current and voltage are used to give correct directional indication for both directional-comparison carrier and for time-overcurrent type of relays.

The authors point out that saturation of current transformers usually occurs at flux densities over 100,000 lines per square inch. They suggest that the figure of 125,000 lines per square inch be used as a criterion. While a figure of 100,000 lines per square inch may be satisfactory for modern current transformers, it may not be satisfactory for some of the older current transformers. About 10 to 15 years ago, a figure of 77,500 lines per square inch represented the saturation flux density of the iron then in use.

The authors point out the value of automatic oscillographs on the power system. In fact, it would be impossible to analyze adequately the difficulties without them. This paper should encourage their more widespread use as a necessary and invaluable tool in analyzing difficult relay problems.

Some of the oscillographs are difficult to follow because of limited explanation and nomenclature. It seems that the value of the paper could be increased in this respect. Along this line, more explanation would be desirable in connection with Fig. 25.

Some of the examples presented produce transients of short duration. As relaying speed increases, examination of these transients becomes increasingly important. These cases again illustrate, we think, that there is a point of no return on increased relay speed. Perhaps there will be a trend away from demanding more speed from the relays and more emphasis on system design which tolerates faults of longer duration.

W. E. Marter (Duquesne Light Company, Pittsburgh, Pa.): Mr. Barnes and Mr. McConnell have presented an excellent discussion of the various difficulties which can occur in the use of ground relays and, in most cases, have suggested corrective measures.

Some recent relay operations on the Duquesne Light Company system indicate that all the problems are not yet solved. In the discussion of magnetizing inrush currents, the authors state that "Little difficulty has been reported of line relay tripouts when energizing a power transformer external to the line." I would like to add two cases to the difficulty already reported.

A 138-kv line terminates in a 100-megavolt-ampere autotransformer bank having a star-star connection and an unloaded delta tertiary winding. The bank has a circuit breaker on the 69-kv bus side, but not on the 138-kv side. The line protection is pilot wire and is fed from 138-kv breaker bushing current transformers on the source end and from 138-kv transformer bushing current transformers on the load end. The transformer was not included in the pilot-wire circuit to avoid the magnetizing-inrush problems. Despite the precautions taken, an operation of the pilot-wire protection occurred when the bank was energized by closing the 138-kv breaker at the source end of the line.

Some tests which have been run indicate that there are at least two factors involved in this problem. First, there is residual magnetism in the bank itself indicated by an oscillograph record in which the exciting current was well above the zero line for several cycles. This type of trouble is discussed in reference 1 and shows a similar condition. The second factor is current-transformer saturation and residual magnetism. The current transformers, although they are both bushing current transformers, are not duplicates since one set is on circuit-breaker bushings and one on transformer bushings.

The second case of pilot-wire relay trouble was very similar to the first, with the exception of the transformer bank connections. A 69- to 23-kv star-delta 30,000-kva bank with only a 23-kv breaker at the bank end of the line, and the bank not included in the pilot-wire protection, was energized by closing the 69-kv breaker at the source end of the line and the pilot-wire relays operated.

In both cases, pilot-wire circuit constants were well within the manufacturers limits and both pilot-wire protective equipments were equipped with phase and ground instantaneous-overcurrent interlock relays. Since one false operation occurred on a *CPD* installation and one occurred on an *HCB* operation, it can be seen that these undesirable currents do not play favorites.

I would like to make one further comment dealing with equation 1. Since system economics will dictate the I and T values, the factors which the relay engineer might improve are the R, N_1, N_2, and A quantities. Any help the current-transformer design engineers can give in increasing the A factor will be appreciated by the relay engineers.

Donn C. Achtenberg (Detroit Edison Company, Detroit, Mich.): Mr. Barnes and Mr. McConnell are to be congratulated for bringing out some information which up to now may not have been considered in analyzing false tripouts by ground relays. This is a subject which needs much discussion.

The Detroit Edison Company has experienced two faults in recent years which may possibly be explained by some of the information from this paper. In one case a 24-kv cable fault caused two 120-kv cables to trip out even though the 24-kv circuit breaker cleared instantaneously. The neutral overcurrent relay on the primary of the 120/24-kv delta-grounded-wye transformer caused the incorrect operation. Also, this neutral relay sent a remote trip signal via pilot wire to trip out the remote 120-kv breaker. The 24-kv fault involved three phases and ground and was in the substation basement. Another 24-kv fault which occurred a short time later but farther "out" did not cause the incorrect operation. It therefore appears that current magnitude is a factor. All current-transformer polarities and secondary wiring were checked and found to be all right. This may suggest, as the authors state in the section entitled "False Residual Current," that false residual current may have been present because of unequal performance by phase current transformers or unequal pole opening of an oil circuit breaker. The delta-connected primary is ungrounded. Two steps were taken to prevent a repetition of this false tripping.

1. The neutral overcurrent relay was changed from an instantaneous type to a time-delay type.
2. An extra step of time was put in to the coil circuit of the auxiliary tripping relays to give a few cycles delay in sending the remote-trip signal.

In another case, false tripping was caused during switching operations to transfer the load of a generator from one bus to another. In this instance, an actual transient voltage was observed on an oscilloscope across the operating coil of a pilot-wire relay. This relay is sensitive to both positive- and zero-sequence currents. Various "pips" could be observed as switching operations were carried out. As the authors state, unequal pole closing or opening of a circuit breaker or disconnect switch could be the cause of such false residual voltages. The duration of the energy on the operating coil was just long enough to close the contacts of the relay. While the contacts themselves opened, the arc established was enough to pick up the auxiliary tripping relay string. The auxiliary string was redesigned from one which normally drew 500 milliamperes d-c to one which draws about 54 milliamperes d-c. This allows the contacts to make momentarily without establishing an arc to cause the auxiliary relay string to pickup. Also, an extra step was put in the auxiliary string as in the foregoing case to delay pickup for a few cycles.

In connection with conclusion 3, it is the practice with this company to order neutral fuse holders for transformers on the subtransmission system if they are to be used in an area where they may be grounded. It is then determined at a later date when the details of the problem are being worked out whether or not a fuse is installed. The factors involved in this determination are the ground-relay co-ordination problem and the voltage on the unfaulted phases for a phase-to-ground fault. We are in agreement with the other conclusions drawn by the authors, especially no. 2.

J. R. Linders (Cleveland Electric Illuminating Company, Cleveland, Ohio): Mr. Barnes and Mr. McConnell are to be complimented for releasing this valuable information to the relaying profession. It will require many more hours of study to appreciate it fully. In spite of the merits of standardization of relay terminals and their calibrations, I fully support the opinion expressed in this paper that ground-relay calibrations should be hand-tailored for each application.

The basic conditions of Fig. 15 become quite complex if one or both circuits are multiterminal. With such a configuration, induced currents can sometimes exceed true fault currents for certain critical fault locations. The false residuals from two circuit faults, as in Fig. 5, can be many times greater than true line-to-ground currents on lightly grounded systems.

I am sure the authors could provide further interpretations to Fig. 21. The tertiary current is not as clean-cut as the text suggests, and it also shows a major alteration at 2 cycles at the same time as the residual-current reversal. Has anyone ever tested the actual performance of a high-speed directional element when subjected to harmonics in the polarizing winding such as shown in trace 2 of Fig. 21? I appreciate the theoretical point that the harmonics result in no net torque on the relay, but has any one made a field test of the phenomenon? Fig. 22 would be considerably more valuable if a sketch of the system and current-transformer connections were provided. As described, the phenomenon completely eludes me.

One other source of false residual currents can be present in a 3-wire current-transformer circuit which uses the station ground as the return circuit for the residual-current path. Voltage drops in the station ground network caused by the main fault-current flow can appear in the residual-relay circuit and cause incorrect performance. Modern practice of 4-wire single-point grounding of current transformer secondary circuits does not have this hazard.

The summaries in Tables I and II are valuable and impressive. Using separate communication channels for phase faults and ground faults can provide a degree of freedom which may be necessary if some of these undesirable factors unexpectedly materialize.

If I were confronted with the requirement for ground-relay sensitivities of the order considered in this paper, I would look fondly at a solution which would utilize electronic phase-comparison relays energized by air-core current transformers.

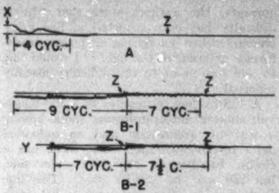

Fig. 29. Cloud discharges on 147-mile 230-kv line with no evidence of actual fault current

A recorded at Crawford Station 8/5/45. B-1 at Powerton Station 4/29/47. B-2 at Crawford Station 4/29/47. Records are from the output of current transformers in the neutrals of the 230-kv terminal transformers
X indicates a deflection equivalent to 130 amperes rms primary current
Y indicates fogged area of record
Z indicates opening of transformer L.T. breakers, as tripped by plunger-type neutral relays, either directly or by carrier remote trip

G. W. Hampe (Commonwealth Edison Company, Chicago, Ill.): This class of problems is analyzed as a group, which is very desirable. I also mentioned some problems in a general way[1] and suggested[2] potential polarization as a remedy. This, as Mr. Kennedy pointed out in his discussion, was not always applicable. It was also suggested that we might protect the three phases, wire by wire, with separate (microwave?) channels, but we have not had to do that yet.

I presented[3] a fault record, taken in May 1940, for line current transients, it is similar to the transformer neutral current in Fig. 4 of this paper, but much higher and longer. It oscillated at a slow rate (4 or 5 cycles per second) and set up an incorrect carrier trip circuit rather late, apparently because, on decaying and oscillating through the values of carrier start and stop, the start and stop elements could not co-ordinate.

I would appreciate an explanation of both the high-frequency oscillations and the slow flip-flops in the voltage traces in Fig. 11. Where line-connected potential transformers or potential devices are used, the slow transients are inevitable and the high-frequency ones quite common. Both occur when the opening of a circuit breaker de-energizes a line.

The authors referred to induction only in terms of induced ground current. It seems possible to have induced residual current without ground current. Consider 2 3-conductor cables on system no. 1 and system no. 2 in the same duct run, each with its own sheath. The phase conductors of the two cables are on systems normally electrically independent, although in the same station at one end. System no. 2 cable is one of several parallel lines between two station busses in that system, with those other parallel lines of system no. 2 geographically remote from the duct run in question. Cable no. 1 has a phase-to-ground fault, with current returning to system no. 1 neutral over the sheaths surrounding the conductors of both system no. 1 and no. 2. There would be induced voltages in the 3-phase conductors of system no. 2 cable. The resulting currents would complete their circuits over the respective phase conductors of the more remote parallel lines. The induced currents would equal an in phase, but on system no. 2 there would be no circuit for neutral or ground current. Since the three induced currents are additive with respect to a residual relay, their effect is appreciable. I used this example to explain some otherwise unaccounted-for relay operations.

To bring in rare cases, the authors might have mentioned the earth currents associated with the aurora borealis, and I can cite two cases even more remarkable. In two cases, during thunderstorms, a 230-kv line apparently discharged through the power transformer neutral at one end. This tripped the plunger-type neutral relay. The line, however, was not faulted. The line discharges as reproduced by the neutral current transformer and transmitted to the relay are shown in Fig. 29. The phenomenon, though rare, bars the use of high-speed ground relaying on that 230-kv line.

All this indicates that applying ground relays is a difficult problem, and when applying fast, sensitive, polarized ground relays, there are considerable uncertainties. At the same time, because of the relative prevalence of ground faults, good ground relaying is very desirable. Perhaps the relative popularity of rather complicated phase-fault relays is that polarizing them and computing their settings is relatively simple.

For 2-terminal pilot-wire protected lines, insurance against the vagaries of system phenomena and current-transformer performances is available,[3] provided one is willing to pay the price, which is that of a sound pilot channel. If carrier pilots are to be used (and this probably includes microwave carrier also), phase comparison seems to be more advantageous. In my experience, some installations of directional- as well as phase-comparison carrier relaying have had a perfect record. On the other installations, after much toil and trouble, both types of relaying (as of the present date) seem to have become quite immune to tripping on external faults. Several directional-comparison applications have a low efficiency on internal faults, and one directional-comparison scheme has had a completely zero efficiency up to now.

On internal line faults it is not easy to shut off a blocking carrier signal and keep it off. After the local circuit breaker opens, it often returns. From this paper some possible reasons for this behavior may be inferred, e.g., when the local trip circuit is energized from any line relay, backups included, an auxiliary relay will turn off the local carrier transmission and hold it off while the local breaker opens and about 15 cycles thereafter. At the end of this period, control would then be returned to the basic carrier controls. This could be applied to both phase- and directional-comparison schemes.

With multiterminal lines becoming more common, if not predominant, the relay engineer's troubles have only started. In discussing a companion paper[4] I make some suggestions of a general nature.

Herbert G. Erdman, Jr. (Public Service Electric and Gas Company, Newark, N. J.): Mr. Barnes and Mr. McConnell are to be congratulated for their excellent presentation of one of the least understood phases of power-line relaying. We have had several cases during recent staged and actual faults on our 132-kv transmission system which involved residual current during phase faults, residual current caused by one open conductor, and incorrect tripping by carrier ground relays during a ground fault.

Fig. 30 is an oscillogram of a phase-1 to phase-2 staged fault on an open-wire 132-kv line. No ground was involved in the fault but the bottom trace indicates 160 amperes in the transformer neutral. After 6 cycles there is a rise in neutral ground current for 1/2 cycle to 1,000 amperes because of unequal circuit-breaker pole opening. The 160 amperes probably result from a combination of unequal charging current and load current in the unfaulted phase 3 and, in this case, are too small to affect relay operation.

Fig. 31 shows a phase-1 to phase-2 staged fault on the remote terminals of an underground pipe-type 132-kv cable. This is an 11-mile circuit having a reactive capacity of 40,000 kva; the 132-kv charging current is approximately 200 amperes. The cable is directly connected to a wye-delta-wye transformer bank and through a 132-kv tie breaker to the 132-kv system at the station where the oscillogram was taken.

After $6^1/_2$ cycles the 132-kv circuit breaker at the remote end of the line and 132-kv local tie breaker had opened. At this time the phase-to-phase fault was being fed only from the low-voltage (26 kv) side of the local bank. The trace of 132-kv neutral ground current shows an increase here from a very low value to approximately 1,600 amperes. An examination of the phase currents in the faulted phases discloses a phase shift at this time from almost 180 degrees out of phase to about 145 degrees. In Fig. 32 these currents are added graphically, including the current in the unfaulted phase 3, producing an indicated residual current of 1,160 amperes. Difficulty in measuring phase angle from the oscillogram makes this result approximate at best; however, the presence of such a high residual current is difficult to explain.

If the foregoing fault were moved beyond the remote terminal of the line and no ground polarizing current appeared at this terminal, directional-comparison carrier relaying would probably not cause incorrect tripping since the phase carrier-starting relays at the remote terminal would send a blocking signal; however if the carrier ground sensitivity were too high or if high-speed backup ground relays were used, false tripping could occur. In any case the co-ordination of phase carrier-starting with ground carrier-tripping elements when the magnitude of ground current is unpredictable is all but impossible.

Previous single-phase-to-ground staged faults on the same cable circuit resulted in three incorrect tripouts of other adjacent line sections. All of these lines are protected with directional-comparison carrier relaying and all tripped at their remote terminals by the operation of carrier ground relays in the absence of blocking. One case was directly traceable to a relay setting which did not cover the operating conditions at the time of the fault. At all of our stations there is only one ground source for all of the 132-kv transformer neutrals and the neutral current transformer thus measures the total neutral ground current of all the banks. Some of these stations are normally operated with the 132-kv bus split in two or more sections but have tie breakers that can be closed at any time. The remote station at which this line was terminated is normally operated with the 132-kv bus split into four sections. The carrier-starting relay is a current-polarized product-type ground relay. At the time of the fault the bus section to which the line was connected was tied to another bus section and the carrier ground relay received much more than normal energy and closed its trip contacts; the ground carrier-starting relay at the local end of the line (also a product type) did not receive enough energy to close its contacts; hence no blocking was transmitted. The co-ordination of elements satisfactory for normal bus operation was upset by emergency operating conditions.

The product-type ground relay has become increasingly difficult to set because of the split bus condition described in the foregoing. It is sometimes difficult to forsee all possible operating combinations. We are now investigating the possibility of controlling carrier with reactance ground relays which require no neutral current or zero-sequence potential for polarization.

The other two lines that tripped incorrectly during a ground fault on the cable apparently received no carrier blocking or received it too late. The carrier-starting elements on these lines are current-polarized directional-overcurrent units. These relays were thoroughly checked and subjected to further staged fault tests but no trouble could be found nor could the trouble be made to repeat itself. Sufficient oscillographic data were not obtained at the time of the initial trouble to discover any condition which might have fooled the ground relays. The fault on the cable circuit was a bolted one and was established by closing the line circuit breaker; therefore the initial surge of current was a combination of fault current and cable-charging inrush. The station bus voltage during this period showed high harmonic disturbances. It appears that high-voltage cable circuits with their high charging capacities will add to the already difficult problem of high-speed ground relaying.

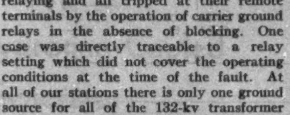

Fig. 32. Graphical addition of phase currents for the phase-to-phase cable fault

H. C. Barnes and A. J. McConnell: We particularly appreciate the corroborative evidence supplied by all of the discussers. Also, we agree with the comments on the following subjects:

1. Value of oscillographs. Merritt, Rockefeller-Blackburn.
2. Current-transformer performance. Marter, Rockefeller-Blackburn.
3. Value of time delay. Merritt, Achtenberg, Rockefeller-Blackburn.

4. Insufficiency of explanation of figures. Rockefeller-Blackburn. (Fig. 25), Linders (Figs. 21 and 22), Hampe (Fig. 11).

With respect to Mr. Erdman's Fig. 31, we believe that the staged phase-to-phase fault became a 2-phase-to-ground fault at the end of 6.5 cycles. At that time, all 132-kv circuit breakers were open, the fault being supplied only through the transformer from 26 kv. The measured ground current was 1,600 amperes, and yet the only outlet (other than a ground fault) was the capacity of the 11-mile cable, the normal charging current of which is only 200 amperes. It is believed that Mr. Erdman's Fig. 32 is incorrect. It will be noted that, beginning at 6.5 cycles, the current in phase 2, Fig. 31, reaches a maximum before the current of phase 1. In Fig. 32, the current in phase 2 reaches a maximum after the current of phase 1. If the phase relationships $I_{\phi 1}$ and $I_{\phi 2}$ of Fig. 32 were interchanged, the resulting phasor diagram would be about the same as would be obtained for a 2-phase-to-ground fault.

With respect to Mr. Erdman's Fig. 30, we believe that the neutral current is simply a result of unbalanced system impedance. If the symmetrical-component method is sound, there can be no neutral current when all impedances are symmetrical.

Mr. Erdman makes a very valuable contribution by suggesting the use of ground-distance relays as a means of carrier control. Ground-distance relays of the current-compensated type require neither neutral-current nor zero-sequence voltage polarization and, consequently, are substantially unaffected by the various ground-relay ills discussed in the paper.

Mr. Rockefeller and Mr. Blackburn contributed the following additional pertinent comments:

1. The use of negative-phase-sequence quantities are effective in the solution of induction problems.
2. Older current transformers should be looked upon with suspicion. Their capabilities are about two-thirds those of modern current transformers.

Regarding Fig. 25, it is first necessary to consider that when the phase-to-phase fault occurs, E_{b-N} (see phasor diagram of Fig. 25), which is the phase *b*-to-neutral voltage, changes in the lagging direction by 60 degrees with a reduction of magnitude to one-half. By the same token, exciting current I_b (during fault without offset) lags exciting current I_b (prefault) by 60 degrees and with magnitude reduced to one-half. When the phase-to-phase fault occurs, the prefault exciting current has a negative value as shown by the solid line. Its ultimate value must be in accordance with the dotted line I_b (during fault, without offset). Since the exciting current cannot change instantaneously, there must be a d-c component called "d-c offset." Thus, for the exciting current to start in accordance with the solid line at the incidence of the phase-to-phase fault and end in accordance with the dotted line I_b (during fault, without offset), there must be the d-c offset as shown. The net result is the dotted line denoted I_b (during fault, with offset). When this exciting current causes the flux to reach the saturating point of the iron, the exciting current will increase while trying to maintain the proper flux,[1] as shown on the curve labelled "magnetizing-current inrush."

Mr. Linders desires further interpretation of Fig. 21. He suggests that something happened to the tertiary current at the end of 2 cycles. We believe that nothing occurred abruptly to the tertiary current at that time. The tertiary current was offset initially and, at the end of 2 cycles, practically all of the d-c component had disappeared. Something did occur abruptly to the phase-1 current after 2 cycles. Calculations have indicated that after 2 cycles, the phase-1 current transformer was residually magnetized so that it could not properly reproduce subsequent half-cycles of current. The current transformers in phases 2 and 3 were still able to reproduce primary current (because of lower current magnitude). Thus, the deficiency in phase 1 caused a reversal in the zero-sequence trace (Musk ground).

With further reference to Mr. Linder's discussion, high-speed directional units have been tested (in the laboratory) to show that no net torque is produced by fundamental current in one circuit and harmonic current in the other circuit. On the other hand, the same harmonic in both circuits will produce torque. We believe that Mr. Linders is suggesting the possibility of harmonic torques being produced by the combination of the tertiary current and the residual current. He is entirely correct in that certain harmonics appear in both currents. Like harmonics will produce a net torque, but the direction of that torque may be either in the tripping or the nontripping direction.

As requested by Mr. Linders, Fig. 34 shows the system and current-transformer connections associated with Fig. 22.

Mr. Linders points out another ground-relay hazard, namely, multiple grounding of the lead connecting the current-transformer neutral and the ground relay or the use of the station ground network as the fourth wire. We believe that such practices are not engaged in today, but it certainly does no harm to warn the younger men against them.

Mr. Hampe requests an explanation of the high-frequency oscillations and the slow flip-flops in the voltage traces of Fig. 11. We would guess that high frequency is a resonant oscillation between the zero-sequence line capacity and the zero-sequence short-circuit inductance of the transformer. This explanation is supported by the fact that current of the same frequency appears in the transformer tertiary. Slow flip-flops might be an oscillation between the line capacity and the magnetizing inductance of the transformer. The peculiar wave shape is explained by the nonlinearity of the magnetizing reactance, the tendency toward a flat top being caused by saturation of the transformer iron. A similarly shaped wave is shown in oscillogram 189-11, Fig. 8;[3] there the phenomenon is called a "ferrononlinear oscillation."

Mr. Hampe makes a real contribution in his discussion of induction with respect to cables in the same duct run. H. R. Paxson of the Philadelphia Electric Company, in an oral comment to the authors, noted a phenomenon akin to induction, but actually conduction. Fig. 35 illustrates the condition. *A* and *B* are nonparallel lines at different voltages. A ground fault occurred on line *B* as shown. Some of the ground current returned to transformer *T* in the normal manner. However, the remainder of the ground current found it easier to return over the phase conductors of line *A*, thereby operating the ground relays on line *A* incorrectly.

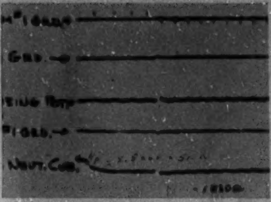

Fig. 36. Example of d-c neutral current caused by unequal pole closing of a circuit breaker

Mr. Hampe's suggestion that carrier transmission be prevented upon tripping a breaker has been used. One operating company had such a difficulty with respect to high-speed reclosing. With a fault near one line terminal, operation at the other line terminal was slow because of low ground-fault current. Carrier transmission from the fast terminal delayed tripping at the slow terminal, thereby reducing the de-energized time sufficiently to preclude successful reclosure. The solution was to prevent the "fast" line terminal from sending a carrier-blocking signal for a short period after tripping.

Fig. 36 is presented to bring the paper up-to-date. In this example, a high-tension breaker was inadvertently closed on a grounded neutral transformer, on the low side of which was a motionless generator. The transformer neutral current (bottom trace) shows an apparent d-c component lasting for at least 1 cycle. This was reproduced on the transient analyzer and was shown to result from unequal breaker pole closing. Ground relays refrained from operating incorrectly, but inadvertent ground-relay operation might have occurred.

We neglected to mention that a sometimes effective method of avoiding false residual current caused by d-c saturation of bushing current transformers is to increase the secondary turns. This method may be particularly effective because the maximum current-transformer flux varies inversely as the square of the secondary turns.

Operation of Hydrogen-Cooled Turbine Generators

C. C. STERRETT
MEMBER AIEE

R. A. TOWNE
ASSOCIATE MEMBER AIEE

HYDROGEN-COOLED turbine generators constitute the major portion of the nation's present generating capacity. Their proper operation is necessary to assure continuity of service to the country and to protect the large capital investment involved in generating equipment. Continuous advances in the design of generators have made it necessary for manufacturers and operators to reexamine operating practices regularly.

In the late 1930's, hydrogen-cooled turbine generators were first put in operation. These units were generally based on load machines operated at 0.5 pound per square inch gauge (psig) hydrogen pressure. They were operated according to the same practices that had been developed over the years for large air-cooled generators. Successful operation was achieved in this manner for these early, relatively small units. To meet the subsequent demand for individual units of higher ratings, manufacturers gradually increased the generator physical size and utilized higher hydrogen pressures. As these larger and more efficient units were placed in service, they were generally utilized for base load operation. The older units were then often assigned to peak load operation, which subjected them to more frequent load cycling. Present operating methods must be reviewed, giving careful consideration to these additional factors, thereby providing increased assurance of continuous service, long life, and minimum maintenance.

This paper is presented to stimulate discussion which will lead to a clearer understanding of the problems involved, and to the development of acceptable operating procedures. A practical method of operating hydrogen-cooled turbine generators is described so as to satisfy present-day operating requirements. A description of the ventilation systems of hydrogen-cooled machines and a discussion of the requirements for successful operation are included. This paper applies specifically to conventionally cooled machines and not to the recently developed machines which embody coil-cooling systems wherein the coolant is brought into more direct contact with the conductors.

Description of Generator Ventilation

Figs. 1(A), (B), (C), and (D) illustrate the arrangement of a typical ventilation system for a hydrogen-cooled turbine generator. The ventilation system is symmetrical about the center of the machine. Hydrogen is circulated by means

Y., January 31–February 4, 1955. Manuscript submitted October 26, 1954; made available for printing December 8, 1954.

C. C. STERRETT and R. A. TOWNE are with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

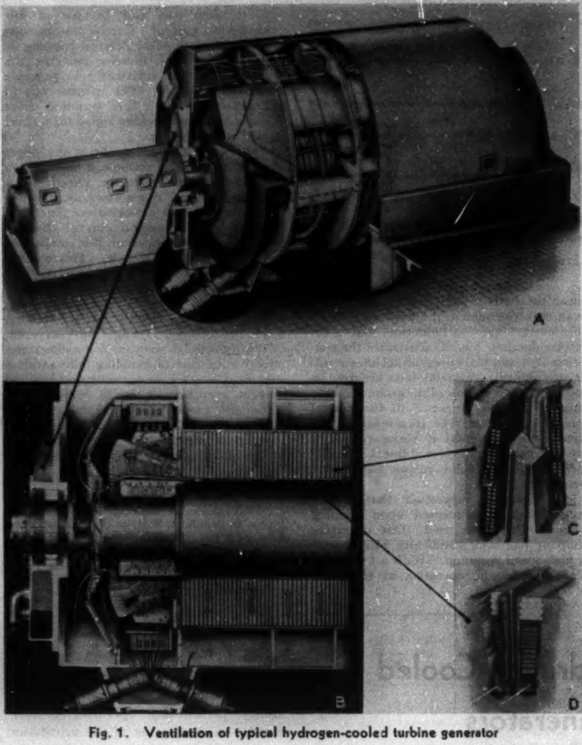

Fig. 1. Ventilation of typical hydrogen-cooled turbine generator

of blowers mounted at each end of the generator shaft. The hydrogen ventilates the rotor and the stator. The entire volume of warm hydrogen is passed through coolers mounted in the generator. The cooled hydrogen is then returned to the blowers. The hydrogen pressure usually can be increased above 0.5 psig to suit the generator loading requirements.

Temperature detectors are embedded in the stator winding to obtain a conventional indication of the temperature of the winding. The rotor temperature is determined from the average resistance of the winding. The cold hydrogen temperature is measured by means of temperature detectors located in the cooler discharge.

Requirements for Successful Operation

The successful operation of a turbine generator requires a consideration of several different factors, a discussion of which follows.

Stator Winding Temperature

The capability of the stator winding is limited by the maximum allowable temperature of the stator insulation. This temperature is maximum at points adjacent to the copper of the winding. The conventional temperature detectors inherently indicate temperatures lower than the copper temperature because of the necessary physical separation of the detector from the stator winding copper. It is a characteristic of hydrogen-cooled machines that the difference in temperature between the detector and the copper is a variable which increases at higher hydrogen pressures. Because of this variation, operation by means of detector indications is undesirable. A means of operating must be provided which effectively supervises the actual stator winding temperature.

Rotor Winding Temperature

Operation at power factors less than the nominal rated value in the overexcited region is limited by the rotor winding temperature. In this region the full rated kilovolt-amperes (kva) of the generator cannot be realized because of this limitation. An operating method must recognize this limitation. The rotor winding temperature does not limit the capability of the generator in other regions of operation.

Stator Core Temperature

Operation in the entire underexcited region is limited by extra heating in the extreme ends of the stator core where temperatures are not detected by the usual stator winding temperature detectors. Due consideration must be given to this effect.

Stator Differential Expansion

The capability of the stator winding is limited not only by total temperature but also by the effects of cyclic differential expansion between the stator coils and the stator core. Differential expansion is a function of the temperature rise of the winding. This requires that the maximum load of the machine be limited so as to limit differential expansion, and that changes in load be made so as to minimize cyclic variations in differential expansion.

The effects of high total winding temperature and frequent variations in differential expansion may result, in some cases, in separations in the stator coil insulation. The stator-coil insulation-separation problem is discussed in detail in a companion paper.[1]

Shaft Alignment

The generator and turbine shafts are solidly connected by means of a bolted flanged coupling. During operation, these shafts must be closely aligned. Misalignment may cause shaft stresses and a redisitribution of the bearing loading, both of which may be excessive and lead to a mechanical failure.

The variation in elevation of the generator shaft is a function of the temperature of its supporting members. The temperature of the bracket and the frame which support it varies directly with the cold hydrogen temperature. Consequently, the generator shaft elevation varies directly with the cold hydrogen temperature. The generator should be operated so as to minimize the possibility of misalignment between the generator and turbine shafts during load changes.

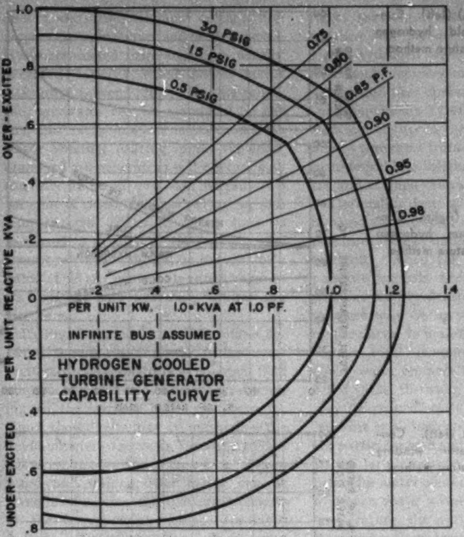

Fig. 2. Hydrogen-cooled turbine generator capability curve

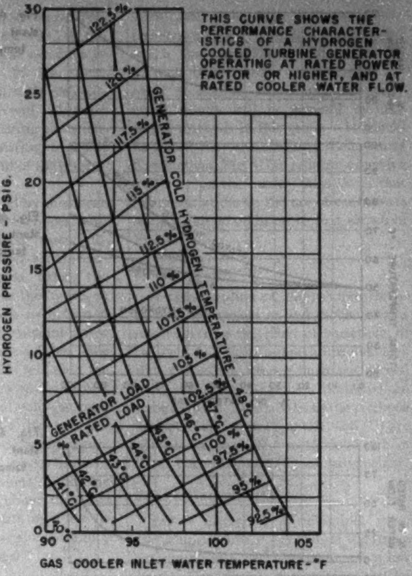

Fig. 3. Typical hydrogen-pressure regulation curve

Frame Distortion

Changes in the cold hydrogen temperature cause distortion of the frame ends, with consequent working of the mechanical joints and gaskets. This may result in increased hydrogen leakage and maintenance. The performance of the gaskets is also adversely affected by high temperatures. The generator should be operated so as to limit frame and gasket distortion.

Condensation on Water Pipes and Frame

Operation of the hydrogen coolers with water colder than the dew point of the room air will cause objectionable condensation on the water pipes and frame.

Operation by Capability Curves

A typical generator capability curve is shown in Fig. 2. This curve should be used to control the operation of the generator under all load conditions, as explained in the following.

Control of Stator Winding Temperature

Since the stator winding temperature detectors do not give a true indication of the winding temperatures, the machine should be loaded in accordance with the manufacturer's capability curve. The capability curve controls operation in the overexcited range from rated power factor to unity power factor by limiting the kva output, thus limiting heating in the stator winding. Temperature readings should be taken and recorded by the user, but their primary purpose should be to indicate incorrect operation or changes in the generator. Therefore, temperature readings are recommended as a backup protection for the hydrogen-cooling system and capability curves.

It is now standard practice to embed 12 stator temperature detectors in the armature winding. They consist of 10-ohm resistance coils located in slots between the two armature coils, and distributed around the periphery and along the length of the stator. Usually five of these resistance temperature detectors are connected to a continuous recorder which gives an indication of the stator winding temperatures. The five highest reading detectors are selected for recording. There are also two cold-gas temperature detectors, one at each end of the generator located in the cold-gas stream entering the blowers. These are generally connected to the same recorder as the stator temperature detectors.

Control of Rotor Winding Temperature

The capability curve should be used to control operation in the overexcited range below rated power factor. It limits the rotor current to a constant value as determined by heating occurring in the rotor winding.

Rotor temperature is usually indicated by a recorder which measures the resistance of the rotor field at a given time and compares it with a known resistance at a definite temperature. Calibration of the rotor temperature recorder may be obtained periodically by determining the rotor resistance from the collector ring voltage and field current with portable instruments.

Control of Stator Core Temperature

The usefulness of the capability curve as a control device is further exemplified in the underexcited region where the underexcited capability shown limits the heating in the stator-core end zones to acceptable temperatures.

Use of Capability Curve

The control of the generator according to capability curves in terms of kilowatts and kilovars may be accomplished by

meters measuring terminal voltage, line amperes, power factor, and field amperes. Hydrogen-cooled generators are usually operated between rated power factor and unity power factor. In this range, the generator can be controlled by the terminal voltage and line amperes since the stator winding heating limits the load. Standard a-c generators will operate successfully at rated kva load within ± 5 per cent of rated terminal voltage at safe temperatures. Thus, if the voltage is increased to a value of 105 per cent, the armature current should be reduced to a value of 95 per cent of its rated value to stay within safe operating limits, and vice versa.

In Fig. 2 the portion of the curve between 0 and rated power factor overexcited can be thought of as constant field ampere limits at the ratings corresponding to the various hydrogen pressures. Thus, these limits may be marked on the field ammeter to serve as operating guides. Likewise, the portion of the curve between rated and unity power factor can be thought of as constant line ampere limits at the corresponding ratings for rated voltage. Therefore, these limits may be marked on the ammeter to serve as operating guides. Since the terminal voltage may vary 5 per cent at rated kva at safe temperatures, it follows that the line ampere limits must be compensated for operation at other than rated voltage. This can be accomplished by using color bands on the meter extending ± 5 per cent of the rated line amperes. Corresponding bands may be placed on the terminal voltmeter. For example, the ammeter would have a 95-per-cent limit when the voltmeter is being held at 105 per cent of rated voltage.

USE OF HYDROGEN-PRESSURE REGULATION CURVE

A hydrogen-pressure regulation curve is shown in Fig. 3. This becomes of interest for operation at higher hydrogen pressures. This curve shows the relation between maximum load, maximum permissible cold-gas temperature, water temperature, and hydrogen pressure. The rated quantity and the rated temperature of water required by the generator gas coolers are such as to absorb full load generator losses and maintain the cold-gas temperature at 40 degrees centigrade (C) at 0.5 psig. It will be noted that, as the hydrogen pressure is increased along the 90-degree-Fahrenheit cooler-water temperature ordinate, the permissible load increases and these increments correspond to the capabilities indicated in Fig. 2. Also, this curve shows that the generator cold-gas temperature will increase above 40 C at the higher hydrogen pressures at rated water flow and temperature. It has been determined that operation with the cold-gas temperature at 48 C will not cause sufficient change in the bearing elevation, due to generator frame heating, to result in undesirable misalignment of the generator and turbine shafts.

The loading demonstrated by this curve is based on the total stator copper temperature being maintained essentially constant. When the cooler-water temperature exceeds the rated value, the machine may be derated or the hydrogen pressure may be increased, as indicated on the curve, to maintain constant stator copper total temperature. When the cooler-water temperature is less than the rated value, the water flow to the coolers may be reduced until the cold-gas temperature is as indicated by the curve for the particular load and hydrogen pressure. In the latter manner the curve becomes useful for water conservation. When the hydrogen cooler-water is above the rated temperature, the water rate may not be increased without incurring the possibility of cutting the cooler tubes.

Operation of Hydrogen Coolers

The control of the water flow to the hydrogen coolers provides a means of regulating the cold hydrogen temperature at partial loads. The water flow is maintained constant at the rated value for loads above the 0.5 psig rating. The control of the cold hydrogen temperature at partial loads involves a consideration of the requirements of stator differential expansion, shaft alignment, frame distortion, and condensation. Such a consideration indicates that operation at a constant cold hydrogen temperature should be recommended as providing the most satisfactory operating results. The basis for this recommendation is discussed in the following.

STATOR DIFFERENTIAL EXPANSION

The differential expansion between the stator winding and the stator core can be controlled to a certain extent by regulating the cold hydrogen temperature. Figs. 4(A), (B), (C), (D), and (E) illustrate the calculated generator temperatures and cooler-water flows at partial loads corresponding to several methods of control. Differential expansion is a minimum with constant stator winding temperature control, but requires prohibitive temperatures in the generator components at partial loads, and is, therefore, unacceptable. The other methods of control shown on Fig. 5 fall in a group within which the variation of differential expansion between one method and another is minor. Therefore, practically equal results will be secured by any of the methods in this group. It should be noted that the constant cooler-water flow method, Fig. 4(D), requires excessive water at partial loads. Also, note that many variations in the use of condensate are possible in addition to that shown in Fig. 4(E).

SHAFT ALIGNMENT

A consideration of the relative elevations of the generator and turbine shafts resulting from the effect of variations in the cold hydrogen temperature indicates that the cold hydrogen must not exceed 48 C if shaft misalignment problems are to be avoided. On this basis the methods of control shown in Figs. 4(B) and (C) are not acceptable. The methods shown in Figs. 4(A), (D), and (E) are satisfactory.

FRAME DISTORTION

Frame distortion is minimized when the temperatures at the ends of the frame are maintained nearly constant at a low level. The frame temperature varies approximately with the cold hydrogen temperature. Operation in accordance with methods shown in Figs. 4(B) and (C) is undesirable. The other methods are considered to be acceptable.

CONDENSATION ON WATER PIPES AND FRAME

It is desirable to avoid operation with the generator cold hydrogen temperature below 25 C to prevent condensation.

RECOMMENDED METHOD OF OPERATING HYDROGEN COOLERS

It is evident that no simple method of operating the hydrogen coolers will satisfy all of the preceding considerations. However, constant cold hydrogen temperature operation or any method which approximates this, such as shown in Figs. 4(A), (D) and (E), provides a means of control for partial load, which is a practical compromise and is, therefore, recommended.

A General Consideration of Generator Operation

As load is assumed by a generator, the cooling water should be gradually admitted to the hydrogen coolers so as to obtain a cold hydrogen temperature in the order of 35 to 40 C. As load is increased, additional water should be admitted so

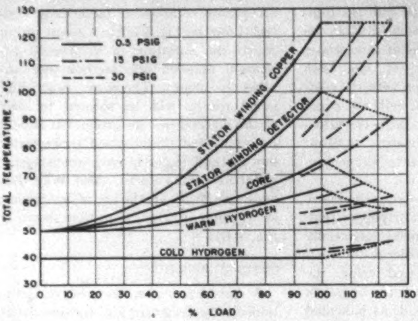

Fig. 6 (left). Typical temperatures and cooler-water flow for hydrogen-cooled turbine generator

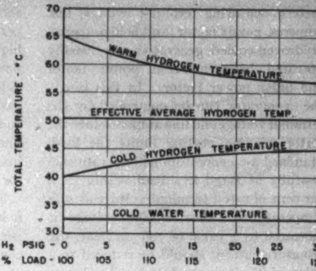

Fig. 7 (right). Variation of cold hydrogen temperature with hydrogen pressure

as to maintain the cold hydrogen temperature approximately constant.

At partial generator loads, the generator losses are reduced, permitting the coolers to be operated at less than rated conditions. A constant cold hydrogen temperature may be maintained with either a reduced water flow at the rated temperature, or an increased water temperature at the rated flow. Where the water supply temperature is considerably below the rated water temperature of the cooler, the water flow should be reduced below rated flow to maintain the recommended cold hydrogen temperature. As the cold hydrogen temperature of a generator responds slowly to changes in load, manual control of the generator temperature will be satisfactory; however, automatic control may be installed if desired. In either case, the cold hydrogen temperature should be used as the basis for regulation.

Constant cold hydrogen temperature control should be maintained up to and including the rating for 0.5 psig hydrogen pressure. For loads greater than the 0.5 psig rating, the hydrogen pressure must be increased according to the capability curve. The generator and cooler are designed so that no further increase in water flow is required for operation above the 0.5 psig rating.

Fig. 6 shows typical temperatures and cooler-water flow at various loads and hydrogen pressures. It will be noted that the stator winding copper temperature is constant for loading about the 0.5 psig rating. It will also be noted that the stator winding temperature detectors indicate unusually low temperature rises at the higher hydrogen pressures. The difference of temperature between the stator winding temperature detectors and the stator copper temperature is of the order of 25 C at 0.5 psig; and difference increases at higher hydrogen pressures, being approximately a function of the square of the current. This curve also shows that the cold hydrogen temperature increases above 40 C when the machine is operated at hydrogen pressures and corresponding loads higher than the basic rating at 0.5 psig. This behavior may be explained as follows:

When a machine is operated at hydrogen pressures above 0.5 psig with correspondingly higher loads, the increase in losses in the machine is approximately balanced by the increase in heat-transfer capability of the hydrogen coolers. Therefore, the difference between the average cooler-water temperature and the average hydrogen remains approximately constant. However, the ability of the hydrogen to absorb heat increases much faster than the losses in the machine for any given increase in hydrogen pressure, with the result that the temperature rise of the hydrogen decreases with increasing hydrogen pressure. Since the average temperature of the hydrogen remains approximately constant, the reduction in the hydrogen temperature rise results in an increase in cold hydrogen temperature, and a decrease in hot hydrogen temperature at higher hydrogen pressures. Fig. 7 shows the general nature of this phenomenon. The conventional increases in rating at higher hydrogen pressures were established by including this effect. It would require coolers of nearly double the usual size to maintain a 40 C cold hydrogen temperature at the 30 psig rating. This would increase the diameter of large machines unreasonably, with no extra advantage to the operator, since present temperatures are satisfactory.

When a generator is expected to carry loads in excess of the 0.5 psig rating regularly, it is common practice to maintain the hydrogen pressure constant at a value corresponding to this peak load. It is uneconomical to reduce this pressure for short-duration reductions in load. Under these circumstances, temperatures corresponding to the dotted lines in Fig. 6 indicate the trend of temperatures which will be obtained.

When load is being dropped from a unit prior to shut down, the water flow should be gradually reduced so as to maintain a substantially constant cold hydrogen temperature.

It should be noted that the diagrams included in this paper have been drawn so that the temperatures correspond to the proposed revision of the ASA *C50* standards[2] for hydrogen-cooled machines. Commercial machines will operate at temperature within these limits.

Summary of Operating Instructions

The generator should be operated in accordance with the generator capability curve with rated flow in the hydrogen coolers except that, for loads up to and including the 0.5 psig rating, the cooler-water flow should be regulated so as to maintain the cold hydrogen temperature at a substantially constant value in the order of 35 to 40 C.

Discussion

M. S. Schneider (Cincinnati Gas and Electric Company, Cincinnati, Ohio): This is a timely paper and should be of great help to all operators of hydrogen-cooled generators. The authors apparently intend that the field loading limits should be determined by field temperature as measured by field resistance as the prime guide and the field ammeter as a check guide. The ammeter scale is to have the limits of operation indicated on it by colored marks. The capability curves in the paper are drawn for only three hydrogen pressures so I am assuming that only three marks would be required on the ammeter.

Since actual gas pressure rarely ever corresponds to the three pressures given in the paper, for the machines on our system, the operators will be required to use loading curves, which are being prepared by our Operating Engineering Section. The use of marks on the ammeter scales would result in so many points that it would be confusing.

Just last week I checked the hydrogen pressures and the resultant usage of the gas for the three units at the Walter C. Beckjord Station. The results are shown in Table I.

The quantities of gas required for higher pressures would be considerably greater and that is why the operating pressures are kept down. The system megavar requirements are such as to permit carrying field currents below rated values.

For us it would be highly desirable if curves of maximum field current versus hydrogen pressure would be provided by the suppliers of the equipment so as to give a separate field capability curve for operating over the entire overexcited region. Field temperature data should also be given for specified machines. I also wish to point out the desire for embedded temperature detectors for the clamping fingers and end iron in the stator for low excitation operation.

It is our opinion that a transmitter sending the hydrogen pressure to the control room from where the loadings of the machines are handled would be a definite aid to the operators. This intelligence should be transmitted electrically as distances are too great for satisfactory use of the pneumatic devices we now have.

I now have two questions with respect to the field temperature recorder:

1. Why do the authors suggest periodic calibration of the field temperature recorder with portable instruments and what length of period is recommended?
2. What is the recommendation for connection of the leads for the field voltage, i.e., main brushes or pilot brushes? Which gives the least trouble and has the least possibility of error?

Table I. Hydrogen Pressures at Beckjord Station

	Rating		Loading		Hydrogen Used,
Unit No.	Megawatt	H_2 Pressure, Psig	Megawatt	H_2 Pressure, Psig	Cubic Feet per Day
1	100	15	100	8	200±
2	100	30	100	10	200±
3	125	30	125	25	400±

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): In the section entitled "Operation of Hydrogen Coolers" in this interesting paper, the authors give reasons for not operating armatures with constant detector temperatures nor constant outlet-hydrogen temperatures. Have there been some unsatisfactory operating experiences or factory test observations with such practices?

The authors recommend operation with practically constant inlet-hydrogen temperatures such as 35 to 40 C at 1/2 psig pressure. We have controlled the water flow to produce inlet-hydrogen temperatures of 30 to 32 degrees throughout the load range for some of our large units. This has been done for hydrogen pressures of 10 to 15 psig as well as for operation at 1/2 psig. Comments on these practices would be of interest.

C. C. Sterrett and R. A. Towne: We wish to express our appreciation for the interesting and constructive discussions. Mr. Schneider states that we apparently intend that the field loading limits should be determined by field temperature as measured by field resistance as the prime guide, and the field ammeter as a check guide. We recommend that the capability curve be the prime guide in conjunction with the use of the field ammeter, and that the field temperature be used as a check guide. With respect to Mr. Schneider's suggestion that curves be provided showing the maximum field current versus hydrogen pressure, we agree that such curves would be a convenience to the operators when they do not wish to interpolate between the rated pressure values.

Thermocouples for supervising the temperature of the stator core end zones are available if desired. The capability curve provides a means of controlling the temperatures in the stator core end zones so that the thermocouples would serve as a check guide.

With respect to question 1, we believe that all instruments should have periodic checks made to assure their proper working order. The time interval between these checks should be in line with the operators practice with regard to other instrumentation in the plant.

With respect to question 2, the measurement of field temperature involves the accurate determination of the voltage across the collector rings. This can be measured either from the current-carrying brushes or from pilot brushes which carry no current and are used only to determine the collector ring voltage.

Pilot brushes, when properly maintained, give the most accurate indication of the ring voltage. However, these rings, because they are not carrying current, often in the course of time develop a glaze on their surface. This glaze has a high and variable electrical resistance. It, therefore, can cause an appreciable error in the voltage. This difficulty can be overcome by proper maintenance wherein the glaze is removed either by sanding the brush surface or exerting pressure on the brush, causing the glaze to be worn off by the ring itself.

Voltage determination from the current-carrying brushes is subject to an error resulting from the brush drop. This error is fairly constant and does not vary much from 3 volts. It can be compensated for at full load, and the error at light loads will be small and is also of less importance. In this case, no glaze will develop on the brush and the brush requires no maintenance to obtain constant results. We recommend the latter method of determining ring voltages because no maintenance is required and the brush-drop error can be compensated for. We feel that this is a more desirable method than the use of pilot brushes wherein lack of proper maintenance can lead to erroneous field temperature readings.

Mr. Halperin asked if there has been any unsatisfactory experience because of operation with a constant stator detector temperature or with a constant warm hydrogen temperature. We believe that the principal disadvantage of these methods is that excessive misalignment will exist between the turbine and generator shafts. This is a very real problem. Several instances of mechanical difficulties in the field due to operation in this manner have been corrected by following the recommended operating procedure.

Operation with cold hydrogen temperatures as low as 25 C are generally acceptable. Shaft misalignment can be a problem because of low as well as high temperatures. Therefore extremes in either direction should be avoided. The initial shaft alignment of the turbine-generator unit should involve a consideration of the expected temperature level of the cold hydrogen.

A Circuit Approach to the Analysis of a 2-Stage Dynamoelectric Amplifier

R. W. BURTNESS
ASSOCIATE MEMBER AIEE

THE d-c dynamo is now used in many applications as an amplifier, subject to input signals which vary as a step function, a sinusoid, or as a random-time function which is difficult to describe by a mathematical function. For this reason, its transient and frequency response has been increasingly important as the d-c dynamo has become an integral part of control systems. Dynamos with higher amplification and improved frequency response such as the amplidyne, regulex, and rototrol have been developed and are now found in many of these automatic control systems. The regulex and rototrol may be thought of as special cases of a standard d-c dynamo. An amplidyne, however, is a type of 2-stage dynamoelectric amplifier as are Rosenberg generators and certain metadynes. To improve the operation and increase the applications of the 2-stage dynamoelectric amplifier, a study of the machine from a fresh viewpoint is justified.

For many years the study of machines and of circuits was not sufficiently integrated to produce maximum usefulness and clarity in studying networks involving rotating machinery. As matrix algebra was applied to circuit problems, it became possible to study extremely complicated circuits with minimum error and maximum clarity. In 1951 W. J. Gibbs made use of the matrix method.[1] H. E. Koenig[2–4] used matrix algebra to extend the coupled-circuit viewpoint to induction motors and to d-c dynamos. In this thesis[2] he also indicated how to evaluate the parameters of the machines so that the equations could be studied with the aid of a computer.

At the present time, there are several articles that consider the amplidyne from a viewpoint of network synthesis but contain very little analysis of the amplidyne itself. The amplidyne is considered as a 2-time constant system, one time constant being that of the armature and the other being that of the field. An accurate determination of these time constants from the design of the machine is not indicated. The usual approach neglects coupling between the direct axis and the control fields, and neglects the short-circuited turns caused by commutation. The latter is an inaccurate assumption because these turns are physically situated so that the change in flux density over the area of the coil is quite large under transient conditions, and this situation exists in both quadrature and direct axes.

In the following analysis, a system of matrix algebra, largely developed by Professor M. B. Reed,[5] is used to facilitate writing equations and to give order to complex mathematical manipulation. Thus, not only the main armature circuits but also the short-circuited turns can be considered in the analysis. This paper is then an extension of the coupled-circuit approach into the area of the 2-stage dynamoelectric amplifier. The differential equations developed are general for any type of load impedance or input voltage. These variable coefficient linear differential equations are then transformed into linear differential equations with constant coefficients which can be solved by standard methods. The equations presented determine the complete transient and steady-state response for any condition of load, or any input-voltage function. With the aid of a computer, a complete study of the operation of the machine can be made.

The details of the equations of the following analysis become exceedingly complex and are not of general interest; therefore, only the outline or general method of attacking the problem and the results obtained are presented. Complete details of the succeeding equations can be found in the author's doctoral thesis. The analysis presented points out not only the two primary time constants of the machine but three others as well. Experimental verification of the analysis is included.

Definitions, Assumptions, and Reference System

Any commutating dynamo may be thought of as an amplifier, with a given input function impressed on the field terminals and the output taken from the brushes on the quadrature axis. If these quadrature axis brushes are short-circuited directly or through a series field in the quadrature axis, a strong quadrature-armature reaction flux is produced. If brushes are then placed in the direct axis, a second stage of amplification from the quadrature-axis brushes to the direct-axis brushes is produced. There may or may not be a compensating winding in this circuit to compensate for the armature reaction in the direct axis. The term, 2-stage dynamoelectric amplifier, referred to subsequently as a dynamo-amplifier, applies to this type of dynamo. The Rosenberg generator, metadyne, and amplidyne could then come under this definition. The dynamo amplifier chosen for analysis is essentially a simple amplidyne but, with the compensating terms set equal to zero, it would become a Rosenberg generator.

To develop the differential equations of a dynamo amplifier from a coupled-circuit point of view, the following is assumed to keep the mathematics rigorous. These assumptions may be modified later in the paper to conform to practice.

1. Saturation and hysteresis in the iron are negligible.
2. The machine is completely laminated.
3. The number of commutator segments is divisible by four and all armature turns are similar and symmetrically spaced.
4. The brush has the same thickness as one commutator segment plus twice the thickness of the insulation between segments.
5. The machine stator is symmetrical with respect to the direct axis and also with respect to the quadrature axis.
6. The rotor is assumed to be round and symmetrically located.

The following should also be noted:

1. An equivalent control field is used which causes the same magnetomotive force to exist as does the total of the various control fields which may be incorporated in the design of the dynamo amplifier.
2. The stator poles and stator fields are shown concentrated in Fig. 1, but in practice these poles are usually split and the winding distributed. This, however, makes no difference in the analysis when the coupled-circuit approach is used.
3. In practice, the dynamo amplifier may contain commutating windings and series

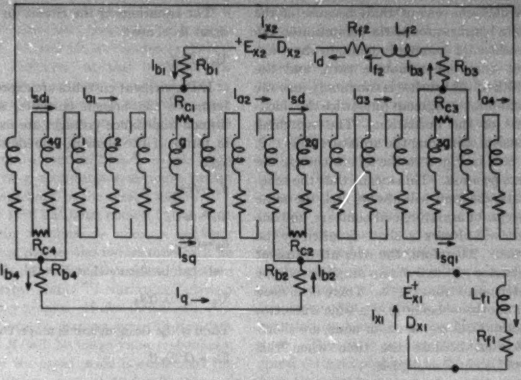

Fig. 3. Schematic diagram of the dynamo amplifier

windings. A basic dynamo amplifier is described which leads to the study of a more complex one.

Fig. 1 represents the physical picture from which a schematic diagram is drawn and which ultimately helps to keep straight the sign of the inductances which vary with time. Fig. 2 shows the width of the brushes and also the lap winding common in a dynamo amplifier. Fig. 3 shows the schematic diagram at time $=0$.

The reference system used is as follows: In any element of a network there may be current, impedance, generated voltages, and impedance voltages. These quantities are represented by I_e, D_e, E_e, and V_e respectively. The impedance D_e represents the derivative function which relates I_e and V_e such that $V_e = D_e I_e$. As illustrated in Fig. 4, an arrow is used to indicate the positive direction of current. The plus sign on the various voltages indicates the actual polarity when the voltage is a positive number.

A branch is defined as the circuit between two nodes, as indicated by large dots in Fig. 3. The same reference system applies to the branch level as to the element level. In writing the equations, the sign of the mutual inductance is included in the M term. Polarity marks are used on each inductance to facilitate the writing of signs included in the M terms when these terms are evaluated. The symbol p is used to represent d/dt.

Nomenclature

Letters denoting matrixes are written in script

Letters other than script refer to terms within a matrix

Subscript e refers to the element level

Subscript b refers to the branch level

Subscript 0 refers to the branch level after variable coefficients have been transformed into constant coefficients

The subscript $_K$ refers to the K level

Subscripts following subscripts e, b, 0, and k in script terms refer to the elements and branches described immediately following equation 16

i and j refer to armature elements where f_1 and f_2 refer to fields

R_b represents the brush and contact resistance in the director of the quadrature axis

R_c represents the brush and contact resistance in the short-circuited turns

T_{fv} = voltage transfer function

T_{fc} = current transfer function

θ = angular displacement of rotor

$\dot{\theta}$ = time rate of change of angular displacement of rotor

ω = angular frequency, radians per second

τ = time constant

Δ = determinant of D_K matrix

Development of Differential Equations

Whenever a commutating machine is operating, there is a small, high-frequency ripple caused by the switching effect as the commutator segments pass under the brushes. Thus, any transient would consist of the over-all transient response with a very high-frequency oscillation superposed on it. To get a workable solution to the problem, the small ripple effect is neglected while the effect of the short-circuited coils on the over-all transient response is taken into account. In the analysis of a dynamoamplifier it is ex-

Fig. 2 (left). View of commutator of the dynamo amplifier

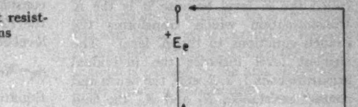

Fig. 4 (right). Reference system for voltages and currents on the element level

tremely convenient that, because of the extra brushes around the commutator, the brushes are commonly made to short-circuit only one armature turn, and the width of the brushes is commonly just one commutator segment plus twice the thickness of the insulation. The switching consists of moving the armature coils 1, 2, 3, etc., in Fig. 3 to the left to occupy the next position. This means that the schematic diagram will always look the same except for armature coil numbers, and one turn will always be short-circuited by the brush. Therefore, the over-all transient behavior of the dynamo amplifier can be determined from Fig. 3. There is no need for another schematic at a time when two commutator segments, or none, are short-circuited because the time when this could occur is negligible.

Part of the small, high-frequency ripple in the transient response is caused by the slight change in inductance and speed voltage components while each commutator segment traverses the distance between switching points. By taking $t=0$ as the time when the machine is half way between switching points and considering the inductances and speed voltage components to be constant over the time between switching instants, and of the same value as when $t=0$, a true representation of the over-all transient is obtained. Thus it is possible to solve the circuit for one position of the armature, at $t=0$, and this linear differential equation with the resulting constant coefficients will represent the over-all transient response of the machine at any time.

The equations of the system are written first on the element level, then transformed to the branch level, and then to a level containing just the currents in the direct and quadrature axes, currents in the short-circuited turns, and current in the control field. This last level is called the K level because it is the K transformation which transforms the branch equations to the K level. The element level includes the individual armature coils 1, 2, 3, etc., the brush and contact resistances R_b and R_c, the field coils, and the two external circuits. The branch level includes the four armature branches between nodes, the four short-circuited coils, the quadrature-axis short-circuited branch between nodes, the direct-axis branch between nodes, the control field, and the external driving circuit. Fig. 4 shows the reference system for voltages and currents on the element level. It is advisable to go through the development of the differential equations by means of matrix algebra to indicate the general method.

The equations of the circuit on the element level are:

$$\mathcal{V}_e=\mathcal{D}_e\mathcal{I}_e \qquad (1)$$

If the element currents are expressed in terms of the branch currents, and the branch impedance voltages are expressed in terms of the element impedance voltages

$$\mathcal{I}_e=\mathcal{A}\mathcal{I}_b \qquad (2)$$

$$\mathcal{V}_b=\mathcal{B}\mathcal{V}_e \qquad (3)$$

$$\mathcal{E}_b=\mathcal{B}\mathcal{E}_e \qquad (4)$$

It can be shown that $\mathcal{B}=\mathcal{A}'$. Thus

$$\mathcal{V}_b=\mathcal{A}'\mathcal{D}_e\mathcal{A}\mathcal{I}_b \qquad (5)$$

Then if the designation is made that

$$\mathcal{D}_b=\mathcal{A}'\mathcal{D}_e\mathcal{A} \qquad (6)$$

equation 5 becomes

$$\mathcal{V}_b=\mathcal{D}_b\mathcal{I}_b \qquad (7)$$

By a method to be described later the time-varying terms in $\mathcal{D}_b$ are transformed to constant terms and the resulting matrix is called $\mathcal{D}_0$. Thus

$$\mathcal{V}_b=\mathcal{D}_0\mathcal{I}_b \qquad (8)$$

Since it has been assumed that the machine is perfectly symmetrical and unsaturated, it can be shown that the quadrature component of current will divide equally in the two armature paths in which it flows. The direct axis current will also divide equally in the two armature paths in which it flows. Also, because of these assumptions, the over-all transient current in the two direct-axis short-circuited coils will have the same magnitude, and the over-all transient current in the two quadrature-axis short-circuited coils will have the same magnitude. Because of the references chosen, the sign of the current in the opposite short-circuited coils is reversed. These considerations make it possible to express the 12 branch currents in terms of 5 K level currents. Thus

$$\mathcal{I}_b=\mathcal{K}\mathcal{I}_K \qquad (9)$$

Equation 8 then becomes

$$\mathcal{V}_b=\mathcal{D}_0\mathcal{K}\mathcal{I}_K \qquad (10)$$

Premultiplying both sides of equation 10 by $\mathcal{K}'$

$$\mathcal{K}'\mathcal{V}_b=\mathcal{K}'\mathcal{D}_0\mathcal{K}\mathcal{I}_K \qquad (11)$$

Now define

$$\mathcal{V}_K=\mathcal{K}'\mathcal{V}_b \qquad (12)$$

Also define

$$\mathcal{E}_K=\mathcal{K}'\mathcal{E}_b \qquad (13)$$

In the particular case of the dynamo amplifier as defined here, and under the assumptions previously listed, it can be shown that $\mathcal{V}_K=\mathcal{E}_K$.

Thus

$$\mathcal{E}_K=\mathcal{K}'\mathcal{D}_0\mathcal{K}\mathcal{I}_K \qquad (14)$$

Then taking

$$\mathcal{K}'\mathcal{D}_0\mathcal{K}=\mathcal{D}_K \qquad (15)$$

$$\mathcal{E}_K=\mathcal{D}_K\mathcal{I}_K \qquad (16)$$

is obtained. Equation 16 is the matrix equation which represents the five simultaneous differential equations of the dynamo amplifier.

Equations 1 through 16 involve an indefinite number of armature coils and the matrixes are large and difficult to handle. To facilitate manipulation, the matrixes on the element level were partitioned into five groups, the numbers of which will be used subsequently as subscripts to element matrixes:

1. Rotor elements.
2. Field elements.
3. Brush resistance and contact drop in short-circuited rotor elements.
4. Brush resistance and contact drop in main rotor elements.
5. External elements.

On the branch level, the matrixes were partitioned into four groups, the numbers of which will be used subsequently as subscripts to branch matrixes:

1. Rotor branches.
2. Short-circuited branches.
3. Stator branches.
4. Main field branches.

Since the machine is assumed to be symmetrical

$$R_{b1}=R_{b2}=R_{b3}=R_{b4}=R_b$$

$$R_{c1}=R_{c2}=R_{c3}=R_{c4}=R_c$$

$$R_1=R_2=R_3=R_4=R_n=R$$

The mutual inductances of the armature coils vary with time as the coils rotate. It can be shown from Fig. 1, and the assumption of symmetry, that the mutual inductances between the armature coils consist of a Fourier series made up of only cosine terms of every other even number; 0, 4, 8, 12, etc. If it is assumed that all armature coils are full pitch coils, the angle between armature coils is $\pi/2g$. Thus the mutual coupling between elements is

$$M_{ij}=\sum_{k=0,4,8,\ldots}^{\infty} M_{ijk}\cos k[\theta-(i+j)\pi/4g] \qquad (17)$$

It can also be shown from Fig. 1, and assumption of symmetry, that the mutual inductance between armature coils and a stator field coil consists of a Fourier series made up of only odd cosine terms. Thus, the mutual coupling between any armature coil and a field coil is given by

$$M_{if_1}=\sum_{k=1,3,5\ldots}^{\infty} M_{ikf_1} \cos k(\theta-i\pi/2g) \qquad (18)$$

$$M_{if_2}=\sum_{k=1,3,5\ldots}^{\infty} M_{ikf_2} \cos k(\theta-i\pi/2g) \qquad (19)$$

Since $\mathfrak{D}_b$ contains both resistance and mutual inductance terms, it can be written as

$$\mathfrak{D}_b=\mathcal{R}_b+p\mathfrak{M}_b \qquad (20)$$

where $\mathcal{R}_b$ and $\mathfrak{M}_b$ are partitioned in the same manner as $\mathfrak{D}_b$. Thus equation 7 may be written as

$$\mathcal{V}_b=(\mathcal{R}_b+p\mathfrak{M}_b)\mathcal{I}_b=\mathcal{R}_b\mathcal{I}_b+(p\mathfrak{M}_b)\mathcal{I}_b+\mathfrak{M}_b p\mathcal{I}_b \qquad (21)$$

since $\mathfrak{M}_b$ contains terms which vary with time. Thus, $\mathcal{R}_b\mathcal{I}_b$ becomes a resistive voltage term, $(p\mathfrak{M}_b)\mathcal{I}_b$ becomes a speed voltage term, and $\mathfrak{M}_b p\mathcal{I}_b$ becomes an inductive voltage term.

Each element of $\mathfrak{M}_{b11}$, $\mathfrak{M}_{b21}$ and of each transpose involves the coupling of armature coils with armature coils, thus following the pattern

$$M_b=\sum_{i=}\sum_{j=}\sum_{k=0,4,8,12\ldots}^{\infty} M_{ijk} \cos k[\theta-(i+j)\pi/4g] \qquad (22)$$

Then, if the derivative of M_b is taken

$$pM_b=\sum_{i=}\sum_{j=}\sum_{k=0,4,8,12\ldots}^{\infty} -k\dot{\theta}M_{ijk}\times \sin k[\theta-(i+j)\pi/4g] \qquad (23)$$

Each element of M_{b13}, M_{b14}, M_{b23}, M_{b24}, and of each transpose involves the coupling of armature coils with a field coil, thus following the pattern

$$M_b=\sum_{i=}\sum_{k=1,3,5\ldots}^{\infty} M_{ifk} \cos k(\theta-i\pi/2g) \qquad (24)$$

Then, if the derivative of M_b is taken

$$pM_b=\sum_{i=}\sum_{k=1,3,5\ldots}^{\infty} -k\dot{\theta}M_{ifk} \sin k(\theta-i\pi/2g) \qquad (25)$$

Each element of M_{b33}, M_{b44}, M_{b34}, and M_{b43} is not a function of time so the pM_b term is zero.

From the examination of Fig. 3, it should be recalled that the armature coils move to the left and occupy the adjacent position in the schematic diagram each time the commutator traverses the distance between switching points. Thus, the mutual inductance between the coils and mutual inductance between each coil and the field coils will change over a complete cycle, in accordance with equations 17, 18, and 19, as θ increases from 0 to 2π. However, as this happens, the coils involved in each branch change in such a way that the coils making up each branch at any time are in relatively the same position. Thus, when looking at the circuit from a branch level, each switch of a commutator segment brings the circuit back to the same location.

Since $t=0$ has been chosen as the time when the machine is midway between switching points, the inductances will be of a value approximately midway between the narrow limits of variation between switching points. If the brush and contact resistance changes over this interval, R_b and R_c will be mean value resistances. Then, if the assumption is made that the speed is kept constant during the time of the transient, $\dot{\theta}$ becomes a constant. Thus, by taking the value of M, pM, L, and R which occur at $t=0$, considering $\dot{\theta}$ as a constant, and using the coefficients derived at this time as constant coefficients of the differential equations, the commutator ripple effect is neglected and the variable coefficient differential equations are reduced to linear differential equations with constant coefficients expressing the over-all electrical conditions in the machine.

Therefore, at $t=0$, equation 22 becomes

$$\sum_{i=}\sum_{j=}\sum_{k=0,4,8,12\ldots}^{\infty} M_{ijk} \cos k(i+j)\pi/4g=M_0 \qquad (26)$$

Equation 23 becomes

$$\dot{\theta}\sum_{i=}\sum_{j=}\sum_{k=0,4,8,12\ldots}^{\infty} kM_{ijk} \sin k(i+j)\pi/4g=\dot{\theta}S_0 \qquad (27)$$

Equation 24 becomes

$$\sum_{i=}\sum_{k=1,3,5\ldots}^{\infty} M_{ifk} \cos ki\pi/2g=M_0 \qquad (28)$$

Equation 25 becomes

$$\dot{\theta}\sum_{i=}\sum_{k=1,3,5\ldots}^{\infty} kM_{ifk} \sin ki\pi/2g=\dot{\theta}S_0 \qquad (29)$$

and $\mathcal{R}_b$ becomes $\mathcal{R}_0$.

Thus, $\mathcal{R}_0$, $\mathfrak{M}_0$, and $\dot{\theta}\mathcal{S}_0$ represent the matrixes containing the branch constants used in further development of the differential equations. The change from pM_b to $\dot{\theta}S_0$ is made to separate the term S_0, which represents a constant of the machine, from $\dot{\theta}$ which represents the presumably constant speed at which the machine is operating.

It should be noted at this point that unilateral coupling is introduced between the field and the armature. Since the armature conductors are continually moving through the field set up by the field poles, a speed voltage is produced in each conductor and thus between armature nodes on the branch level. However, when considering armature current between armature nodes, it is found that the field set up by this current is essentially stationary with respect to the field poles. The only motion is caused by commutation and is at a very high frequency. This component of magnetomotive force does not produce much flux because of eddy currents. The voltage produced in the field windings by this small amount of flux is at such a high frequency that very little change in current results because of the high impedance. Thus it is possible to neglect the speed voltages produced in the field windings by armature current, while speed voltages produced in the armature windings by field current must be considered. This indicates that each speed voltage term $\dot{\theta}S_0$ which gives field voltage in terms of armature current will be zero. The inductive voltage term M_0p will still remain bilateral because the inductive coupling between the armature branches and the field will not be affected.

The shape of the poles and magnetic path as well as the material of the machine will determine M_{ijk} and M_{ifk}. These constants can be determined from the design as indicated by H. E. Koenig.[3] In addition to the previously mentioned positions, there are several positions in the various matrixes that will be zero because of the symmetry of the machine. In equations 26 and 27, M_0 is zero when the short-circuited coils are perpendicular. $\dot{\theta}S_0$ is zero when the short-circuited coils are perpendicular to one another and also when they are in the same axis. This is true because the derivative of the mutual inductance is not changing at this point because of the symmetry of the dynamo. In equations 28 and 29, M_0 is zero when the axis of the coil is parallel to the axis of the field. $\dot{\theta}S_0$ is zero when the axis of the coil is parallel to the axis of the field. Thus equation 21 becomes

$$\mathcal{V}_b=\mathcal{R}_0\mathcal{I}_b+\dot{\theta}\mathcal{S}_0\mathcal{I}_b+\mathfrak{M}_0 p\mathcal{I}_b \qquad (30)$$

or

$$\mathcal{V}_b=\mathfrak{D}_0\mathcal{I}_b \qquad (31)$$

where

$$\mathfrak{D}_0=\mathcal{R}_0+\dot{\theta}\mathcal{S}_0+\mathfrak{M}_0 p \qquad (32)$$

Equation 9 expresses the branch currents in terms of the K level currents. The $\mathcal{K}$ matrix is written in accordance with the discussion preceding equation 7. Combining equations 4 and 13, the expression for $\mathcal{E}_K$ becomes

$$\mathcal{E}_K = \mathcal{K}'\mathcal{A}'\mathcal{E}_e \tag{33}$$

By equation 15

$$\mathfrak{D}_K = \mathcal{K}'\mathfrak{D}_e\mathcal{K} \tag{34}$$

If the foregoing matrix multiplication is carried out, equation 16 becomes

$$\begin{bmatrix} 0 \\ 0 \\ 0 \\ E_{x2} \\ E_{x1} \end{bmatrix} = \begin{bmatrix} D_{K11} & D_{K12} & D_{K13} & D_{K14} & D_{K15} \\ D_{K21} & D_{K22} & D_{K23} & D_{K24} & D_{K25} \\ D_{K31} & D_{K32} & D_{K33} & D_{K34} & D_{K35} \\ D_{K41} & D_{K42} & D_{K43} & D_{K44} & D_{K45} \\ D_{K51} & D_{K52} & D_{K53} & D_{K54} & D_{K55} \end{bmatrix} \begin{bmatrix} I_{sq} \\ I_{sd} \\ I_q \\ I_d \\ I_{f1} \end{bmatrix} \tag{35}$$

The currents of $\mathcal{I}_K$ are the currents in the quadrature-axis short-circuited turns, the current in the direct-axis short-circuited turns, the quadrature-axis current, the direct-axis current, and the main field current, as illustrated in Fig. 3 and described preceding equation 9. The D_K terms are made up of hundreds of terms which contain resistances, inductances, mutual inductances, and speed voltage coefficients, i.e., D_{K35} represents all the terms by which I_{f1} is multiplied to obtain the voltage generated in the quadrature-axis circuit.

Equation 35 gives the five linear differential equations with constant coefficients which state the over-all response of the dynamo amplifier. These equations cannot be solved in general terms because a general formula does not exist which gives the roots of a fifth or higher degree polynomial. However, once numerical values for the coefficients are obtained, the roots of the fifth or higher degree polynomial can be located. The solution to the simultaneous linear differential equations with constant coefficients is a standard procedure and either classical methods or Laplace transform can be conveniently used.

If Δ represents the determinant of D_K, and A_K represents the cofactor of D_K, then

$$\Delta \begin{bmatrix} I_{sq} \\ I_{sd} \\ I_q \\ I_d \\ I_{f1} \end{bmatrix} = \begin{bmatrix} A_{K11} & A_{K21} & A_{K31} & A_{K41} & A_{K51} \\ A_{K12} & A_{K22} & A_{K32} & A_{K42} & A_{K52} \\ A_{K13} & A_{K23} & A_{K33} & A_{K43} & A_{K53} \\ A_{K14} & A_{K24} & A_{K34} & A_{K44} & A_{K54} \\ A_{K15} & A_{K25} & A_{K35} & A_{K45} & A_{K55} \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 0 \\ E_{x2} \\ E_{x1} \end{bmatrix} \tag{36}$$

Equation 36 then gives the differential equations of I_{sq}, I_{sd}, I_q, I_d, and I_{f1}. It can be seen that, if all values of D_K are inductive, the denominator of any D_K term will be one, and the characteristic equation of all the currents will be a fifth-order equation given by $\Delta I = 0$. From this equation the complementary function is found. There must be a negative real part to every root of the characteristic equation to insure stability. If D_{x1} and D_{x2} contain capacitance, p terms will be introduced in the denominators of some of the terms in the cofactor matrix of equation 36. These terms in the denominators will then enter into the characteristic equation and raise the order of the equation higher than the fifth-order equation $\Delta I = 0$.

The correct cofactors properly multiplied by the impressed voltages will give the forcing function which, in conjunction with the characteristic equation, will yield the particular integral. The transient and steady-state responses are then readily obtainable if the forcing function is a step function, a sine function, or another function which lends itself to standard methods of solution. If the forcing function is more complicated, the solution may have to be obtained in a series form.

Although these equations are valid for any load impedance, two common load impedances are mentioned in particular, i.e., dynamo field and dynamo armature. In the case of a dynamo field as load, $E_{x2} = 0$, and $D_{x2} = R_f + pL_f$. The equation of output current then becomes

$$\Delta I_d = A_{K54}E_{x1} \tag{37}$$

where A_{K54} is a fourth-degree expression in p as indicated in equation 35. This equation can be solved as previously indicated.

In the case of a dynamo armature as load, $E_{x2} = 0$, and D_{x2} can be approximated by a parallel combination of R_2 and C_2 which is placed in series with R_1 and L_1. In this circuit, L_1 and R_1 represent the armature inductance and resistance. The voltage across R_2 and C_2 represents the armature generated voltage. C_2 would be proportional to the moment of inertia and R_2 would be inversely proportional to viscous friction in the system. If $L_1/R_1 = \tau_1$ and $C_2R_2 = \tau_2$

$$D_{x2} = \frac{R_2 + R_1(1+p\tau_1)(1+p\tau_2)}{1+p\tau_2} \tag{38}$$

From equation 35 it can be seen that, when D_{x2} is inserted in the D_{K44} term, Δ becomes a sixth-degree polynomial in p because of the second-degree term in the numerator of D_{x2}. The denominator of D_{x2} will then become a multiplier of the right-hand side of equation 37. A_{K54} will not change because D_{K44} is not contained in A_{K54}. Thus, the forcing function becomes $A_{K54}(1+p\tau_2)E_{x1}$ and thereby involves a fifth-degree polynomial in p. Therefore, the determination of the complementary function of equation 37 with a dynamo armature load involves the solution of a sixth-degree polynomial, whereas the determination of the complementary function of equation 37 with a dynamo field involves the solution of a fifth-degree polynomial. The degree of the polynomial on the right-hand side of equation 37 necessary to determine the particular integral would be determined by the function E_{x1}.

When a dynamo amplifier is used in various systems, the transfer function is often desirable. To obtain the transfer function, E_{x2} is set equal to zero and equation 36 yields equation 37. Since

$$V_{x2} = D_{x2}I_d \tag{39}$$

equation 37 becomes

$$\frac{V_{x2}}{E_{x2}} = \frac{A_{K54}}{\Delta}D_{x2} = T_{fv} \tag{40}$$

Since the output impedance of the dynamo amplifier is usually either a dynamo field or a dynamo armature, the output current becomes very important. In a dynamo field, the flux is approximately proportional to current, and in a dynamo armature the torque is proportional to current. Therefore, a more useful transfer function relates output current to input voltage. This transfer function is obtained from equation 37

$$\frac{Id}{E_{x1}} = \frac{A_{K54}}{\Delta} = T_{fc} \tag{41}$$

The voltage transfer function, equation 40, presents a convenient way to determine the gain and phase shift as a function of frequency. The solution of the equations is not necessary. If $j\omega$ is substituted for p in equation 40, a polar plot of gain and phase shift can readily be plotted as a function of frequency.

The foregoing is a general analysis for the type of dynamo amplifier selected for study. The load is completely general and, thus, the analysis is good for any type of load which is put on the dynamo amplifier. With this analysis, it is possible to determine the complete transient and steady-state response as well as the transfer function and frequency response for the dynamo amplifier under any conditions of load and any input-voltage function. This includes the determination of all the currents in the various windings of the machine. The differential equations can be solved by standard methods and it only becomes necessary to resort to series solutions for the particular integral when the input-voltage function is of a rather complicated nature.

The foregoing analysis neglects the ripple caused by commutator action. However, if the branch equations were used directly as in equation 7, and the time-varying parameters were substituted in this equation, a standard mesh transformation could be applied. This would lead to simultaneous linear differential equations with time-varying coefficients. These equations could be solved by a point-by-point process with the aid of a computer. In this manner, the instantaneous currents could be obtained and commutation could be studied. This, of course, would be an extremely difficult problem because the instantaneous values of brush resistance and contact drop would be quite critical, and accurate methods of determining these values are not available.

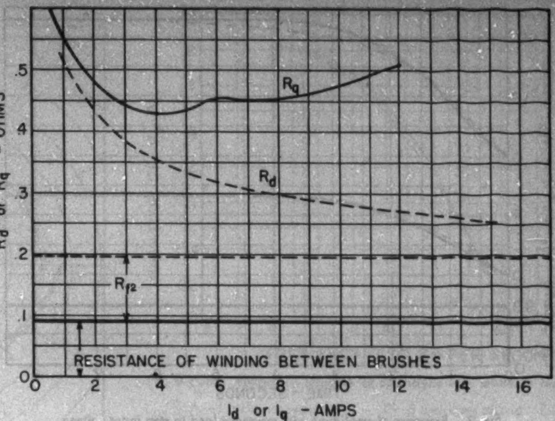

Fig. 6. Armature circuit resistance versus armature current

Experimental Verification of Analysis

When any difficult physical problem is approached from an analytical viewpoint it is usually necessary to make simplifying assumptions to make the mathematics rigorous and to simplify the analytical solution. The basic assumptions must be judiciously chosen so that the final solution will still be reasonably correct. Many electrical problems involve saturation, hysteresis, and variable parameters. Consideration of saturation in a dynamo amplifier becomes impractical from an analytical viewpoint. This is also true of hysteresis and certain types of variations in parameters such as brush resistance and contact drop. It is, therefore, necessary to make simplifying assumptions and then proceed to a rigorous solution of the mathematics involved. The mathematical solution is then used as a basis to study the problem and the effect of various changes in parameters.

After the mathematical solution is thoroughly studied, a machine can be built which has certain parameters in it that can be varied with a slight adjustment. Operating characteristics of the machine are experimentally taken and, with the use of knowledge gained from the mathematical solution, proper adjustment of the parameters is made and the desired operating characteristics are achieved. In any analytical development, it is desirable to know how accurate the basic assumptions are and what values are critical and should be closely watched. Of general interest is the knowledge of how much labor is involved in predicting operating characteristics and how accurate these results are.

Taking the forgoing requirements into consideration, the dynamo amplifier selected for experimental work was a General Electric aircraft amplidyne motor-generator *5AM61NJIC*. The motor-genera-

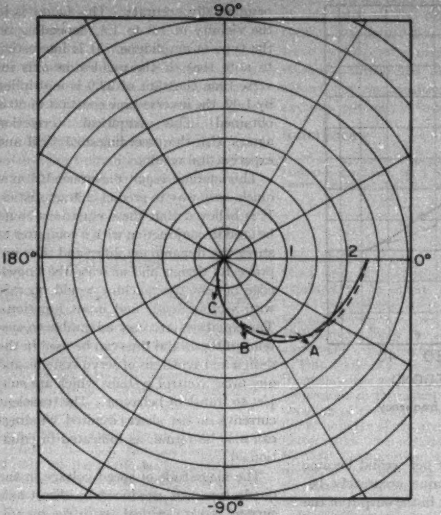
This subcaption also applies to Figs. 9, 10, and 11

tor set is a 2-bearing set, the motor of which is rated at 27 volts, 88 amperes, 6,000 rpm, for 10 minutes. The amplidyne is rated at 60 volts, 1,300 watts, and 21.7 amperes. Because of the high current rating of the motor, it was not used. Instead, a 2-horsepower 3-phase 220-volt 3,480-rpm induction motor was used to drive the amplidyne. By using a motor of this capacity and considering a maximum of 30 volts, 10 amperes at the output terminals of the amplidyne, less than 1-per-cent variation in speed was expected from no load to the maximum load considered on the amplidyne. A speed check later showed about 3,548 rpm at no load and about 3,525 rpm at 30 volts, 10 amperes, or a variation of about two-thirds of 1 per cent. The amplidyne was modified so that it no longer contained a series field in the quadrature axis or a shunt across the compensating winding. The commutator contained 48 bars and the armature was lap-wound. The brush thickness was that of a commutator bar plus two thicknesses of insulation. This amplidyne, therefore, appeared to be very well suited for experimental verification of this article. Preliminary curves were taken on the amplidyne to determine its stability with a resistance load, and to determine the extent of hysteresis in the amplidyne, as indicated in Fig. 5. At this point it could be seen that the machine had a very wide hysteresis loop and that this would be a probable source of error.

Resistances, speed voltages, and inductances were all measured. It was found that obtaining measurements on the element level was impractical because of the influence of the magnetic fields of armature windings. The current in the compensating winding produces a component of flux which directly opposes the armature direct-axis flux and in the *K* level matrix, the net flux becomes important. This amounts to only about 2 per cent of the component of flux in either direction. Therefore, a few per cent error in the element level would completely destroy the accuracy of the *K* level matrix. Thus, whenever possible, measurements were made on the *K* level and values were substituted directly into $\mathfrak{D}_K$. Even with this method, a slight error is introduced because of the slight variation in speed during the transient. The resistances, with the exception of brush resistance and contact drop, were easy to measure. The armature-circuit resistances were obtained with the armature rotating, first in one direction and then in the other direction. The mean resistance was taken to compensate for any generated voltages in the circuit. It was found that the brush resistance and contact drop in the quadrature axis varied substantially from that in the direct axis, as indicated in Fig. 6. It was noted that, when I_q reached about 4 amperes, the amplidyne started to whine. When I_q reached about 10 amperes, sparks were visible at the quadrature-axis brushes. This energy loss caused by poor commutation is probably partially reflected in the high apparent value of brush resistance and contact drop. The inductance of the quadrature axis is very much higher than the inductance of the direct axis because of the opposition and close coupling of the armature winding and the compensating winding in the direct axis. Therefore, it is expected that higher voltages would be generated in the conductors undergoing commutation at the quadrature brushes, and that this would lead to poor commutation. Values of brush and contact resistance representative of the steady state current flowing in the particular circuit were taken from Fig. 6.

For determining the speed voltages present, Fig. 7 was drawn and the speed voltages were given the same polarity as impedance voltages and, thus, considered as such. The armature was rotated at about 3,548 rpm and the various speed voltages were measured with a high-resistance voltmeter and carbon brush probes on the commutator. By dividing the induced voltage by the current producing the field, $\dot{\theta}S$ is obtained. Where there was appreciable hysteresis, as there was when the main field was excited, a curve was taken of induced voltage versus exciting current after demagnetizing the field. Then the linear portion of the curve was used to determine $\dot{\theta}S$. The range of values of self-inductance measurements was from about 100 microhenrys to 500 henrys, so one method of measurement could not be consistently used to obtain all values. To measure the self-inductances of the armature short-circuited paths, the lap-wound armature was opened at a riser and an inductance bridge was used. In this measurement as well as in all others, the value of self-inductance or mutual inductance did not vary appreciably with frequency below 60 cycles because of the laminated structure of the machine. To determine the mutual inductance between armature short-circuited paths, a calibrated variable mutual inductance was used. One coil was put in series with each of the coils of the unknown mutual inductance. A small alternating voltage was put on one series connection and a cathode-ray oscillograph was used across the other series connection as a detector. By varying the calibrated variable mutual inductance, a null point was obtained and the unknown mutual was determined. A very small third-harmonic component was disregarded.

For the other measurements, it was found most convenient to use the voltmeter-ammeter method of determining self-inductance and mutual inductance.



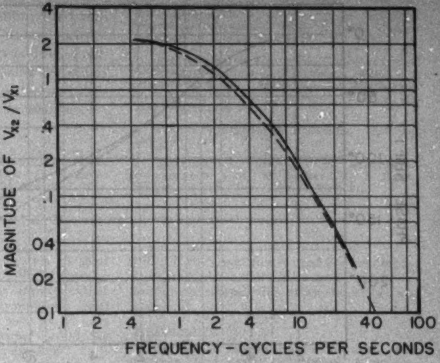


Fig. 9 (left). Frequency response of amplidyne with resistance load

A—1 cycle per second
B—2 cycles per second
C—5 cycles per second

Fig. 10 (above). Gain of amplidyne with resistance load versus frequency

The most critical inductance measurement was that of the main exciting field. It can be seen from the curve in Fig. 8 that a bow exists at the lower portion of the ascending saturation curve. Thus, at low values of alternating current, the inductance would appear unreasonably low because of the slope of the curve near the origin. By using a 60-cycle voltage of 400 volts and no biasing circuit, the current was approximately of the same peak magnitude as the current was when the field had rated direct voltage on it. A trace of the current wave shape was put on a cathode-ray oscillograph and it did not seem to differ from the trace of a sinusoidal voltage wave. The resistance was negligible, and the impedance was considered practically all reactance. In this way, a value of inductance was obtained which is considered representative of the operating current range of the exciting field, or at least it represents a kind of average over the full range of values.

The response of the amplidyne to an input step-function voltage of 9.9 volts, with a resistance load of 2.3 ohms, was chosen for prediction so that the currents involved would not cause the iron to approach the saturation point. The machine constants were then substituted into equation 35 as follows

$$\begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 9.9 \end{bmatrix} = \begin{bmatrix} 0.356+0.128q & 0 & -1.21q & 0 & -26 \\ 0 & 0.096+0.36q & 0 & -0.37q & 62q \\ -1.21q & 0 & 0.436+11.5q & -0.061 & -910 \\ 0 & -0.37q & 4.58 & 2.58+1q & 0 \\ 0 & 62q & 0 & 0 & 2970+393\times 10^{3}q \end{bmatrix} \begin{bmatrix} I_{sq} \\ I_{sd} \\ I_q \\ I_d \\ I_{f1} \end{bmatrix} \qquad (42)$$

where $q=10^{-3}p$. Equation 42 was then used to determine Δ.

Thus

$$\Delta=-0.04\times 10^{-12}p^5-13.7\times 10^{-9}p^4+675\times 10^{-6}p^3+409\times 10^{-3}p^2+21.1p+143 \qquad (43)$$

The p^5 and p^4 terms involve accumulated errors from each inductance measurement and are somewhat inaccurate. They do not affect the response except at high frequency, so to calculate a predicted response, these terms were dropped. The remaining expression then has roots of −7.5, −50, and −548. An approximate solution to the characteristic equation $\Delta I=0$ is then

$$I=A_1\epsilon^{-7.5t}+B_1\epsilon^{-50t}+C_1\epsilon^{-548t} \qquad (44)$$

Upon inspection of the right-hand side of equation 37 and considering that E_{s1} is a step function that is constant after $t=0+$, the only term of A_{K54} that enters the equation is the constant term. The constant term of $A_{K54}=-142$. Then, by equating the constant terms of equation 37, the particular integral becomes

$$I_d=-9.84 \qquad (45)$$

The complete solution for I_d is

$$I_d=A_1\epsilon^{-7.5t}+B_1\epsilon^{-50t}+C_1\epsilon^{-548t}-9.84 \qquad (46)$$

From equation 39

$$V_{x2}=A\epsilon^{-7.5t}+B\epsilon^{-50t}+C\epsilon^{-548t}-22.8 \qquad (47)$$

Before the step-function voltage is applied, all the currents in the amplidyne are considered to be zero, and thus the various derivatives of the input current are zero at $t=0+$. Substitution of these conditions into equation 47, and solution for A, B, and C shows that C is extremely small, and the term $C\epsilon^{-548t}$ is negligible. Thus equation 47 becomes

$$V_{x2}=26.8\epsilon^{-7.5t}-4.03\epsilon^{-50t}-22.8 \qquad (48)$$

This equation is plotted in Fig. 8. In the foregoing manner I_q is also determined to be

$$I_q=-6.51\epsilon^{-7.5t}+0.98\epsilon^{-50t}+5.55 \qquad (49)$$

This equation is also plotted in Fig. 8.

Equation 40 shows the voltage transfer function of the amplidyne. With the resistance load previously under consideration, T_{fe} becomes approximately

$$T_{fe}=\frac{582\times 10^{-3}p+328}{675\times 10^{-6}p^3+409\times 10^{-3}p^2+21.1p+143} \qquad (50)$$

$$=862\frac{(p+564)}{(p+7.5)(p+50)(p+548)} \qquad (51)$$

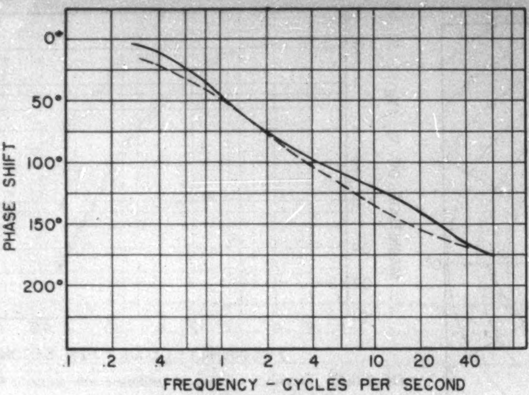

Fig. 11. Phase shift of amplidyne with resistance load versus frequency

Since the $(p+564)$ term and the $(p+548)$ term are so nearly alike, practically all the effect of these terms on phase shift and amplitude will cancel in the range below 60 cycles. Thus for this frequency range

$$T_{fv}=\frac{862}{(p+7.5)(p+50)} \qquad (52)$$

Magnitude and phase of the transfer function are plotted against frequency in the polar plot in Figs. 9, 10, and 11.

Experimental data were also taken on the amplidyne with a step-function voltage of 9.9 volts applied, and a resistance load of 2.3 ohms. A Hathaway recording oscillograph *S-14a* was used to record E_{x1}, I_q, and V_{x1}. The results are shown in Fig. 8. A frequency response was taken with the aid of a Hewlett Packard low-frequency oscillator *202 B* to generate E_{x1}, a cathode-ray oscillograph to measure voltage, and the recording oscillograph mentioned in the foregoing to record phase displacement. This frequency response is plotted in Figs. 9, 10, and 11.

Analysis of Results

Usually the amplidyne is considered as a 2-time constant system. The preceding experimental work verifies this fact when low frequencies are involved. The experimental work does not show the presence of the other three time constants which are noted in the analysis. The reason for this is that these time constants do not become effective either in phase or amplitude in the amplidyne under consideration until the frequency is above 60 cycles per second. Experimental data above 40 cycles per second became impossible to determine accurately because of noise present in the output of the machine. It is interesting to note that the inverse-time constants of each circuit, as indicated on the main diagonal of equation 42, are 2,780, 706, 37.9, 2,580, and 7.57. The inverse-time constants considered in the solution of Δ were the primary root 7.5 and the secondary root 50. It is evident that the main field is the major contributing factor to the primary root. It is also evident that the quadrature-axis inverse-time constant is the major contributing factor to the secondary root. However, it should be noted that the secondary root, which could be termed the armature inverse-time constant in a 2-time constant system, does not come directly from a specific circuit time constant, but is contributed to by several circuits and the coupling between these circuits. The secondary root is between the quadrature-axis inverse-time constant and the inverse-time constant of the short-circuited turns in the direct axis. It can, therefore, be concluded that the short-circuited turns in the direct axis have a definite bearing on the magnitude of the secondary root, and disregarding these turns can lead to considerable error in the armature time constant.

Some engineers have found that the armature quadrature-axis time constant does not give sufficiently accurate results in conjunction with the field time constant when considering the transfer function. An experimental factor has been used as a multiplying factor by which the quadrature-axis inverse-time constant is multiplied to obtain a value which is experimentally accurate. This factor is in the vicinity of 1.3 to 1.5, depending on the type of amplidyne. It is interesting to note that, if the quadrature-axis inverse-time constant of 37.9 is multiplied by 1.32, the inverse-time constant of 50 is obtained. This empirical correction agrees with the preceding analytical and experimental results.

This method is not recommended as a quick, easy way to predict characteristics. It is believed that these equations could be used in conjunction with a computer to study the dynamo amplifier and thus improve its design and increase the knowledge of how the machine would operate with various loads and input functions. The equations are very adaptable to system synthesis and thus can be used in the design and synthesis of servo systems and any other control systems which are subject to transient behavior. The transient currents in the short-circuited windings can also be found, as indicated in equation 36.

The magnitude of speed voltage in the quadrature axis produced by direct-axis current is very critical, as in the magnitude of the inductance of the main field and the magnitude of the coupling between the main field and the direct axis. The magnitude of this coupling should be small to give good stability. This coupling was negligible in the amplidyne under consideration. The armature resistance must be carefully measured as it varies widely over a common range of currents, as shown in Fig. 6. Inaccuracies in armature resistance affect both steady-state and transient results. The speed is involved in the speed voltages mentioned in the foregoing and is very important. The wide range of inductance measurements lead to measurement difficulties, but a reasonable error in quantities other than those previously mentioned does not lead to considerable error in the final results.

Conclusion

In the preceding analysis, the 2-stage dynamoelectric amplifier has been approached from a coupled-circuit point of view. Differential equations, taking into account currents in the coils undergoing commutation, have been written which are general for any type of load impedance or input-voltage function. The equations were then transformed to linear differential equations with constant coefficients. The currents in the various windings are then obtainable. The expressions for transient and steady-state response are developed along with the transfer function which gives the frequency response.

Experimental data to determine the transient and frequency response of an amplidyne were taken. Calculated and experimental curves are shown to agree within the limits of experimental accuracy. It is concluded that neglecting the armature short-circuited turns caused by commutation leads to considerable error in the value of the armature time constant. It is hoped that this analysis will serve to deepen the understanding of a 2-stage dynamoelectric amplifier as well as extend the applications of the coupled-circuit viewpoint in machine analysis.

◆

Discussion

Robert M. Saunders (University of California, Berkeley, Calif.): The author has undertaken a difficult but essential work in any control system component synthesis. In the inexorable demand for a transfer function for the 2-stage dynamoelectric amplifier, the systems engineer has turned to network or "black-box" synthesis as the most readily available means at hand. In his own mind the doubt always remains that his transfer function thus determined is valid only for the particular component he dealt with. Thus, it is essential that the transfer function be developed from the "inside out," so to speak, rather than from the "outside in."

Yet I am left with a definite feeling of uncertainty as to the validity of the author's results. Many of the assumptions he has made are suspect and some have even been shown to be untenable by the end of the paper, e.g., hysteresis. Others regarding eccentricity, absence of direct-axis interpoles are known at the outset to be shaky. The fact that the author was able to check his own experimental results validates his assumptions for his case only and does not provide the designer with the necessary universal means of extending himself into the unknown. On the positive side, by means of coupled-circuit theory, the author has validated the network synthesis transfer function within the assumption structure he has imposed.

G. H. Fett (University of Illinois, Urbana, Ill.): Dr. Burtness has shown that even the complicated 2-stage dynamo amplifier can be analyzed as a type of coupled electric circuit. His paper points out again how the problem of including speed voltage, mutual inductance, and load impedance voltage drops can be solved when the matrix method is adopted.

One caution must be interjected. The problem of measuring the constants required is a very difficult one to solve and the values obtained may be quite in error. The phase-shift curves obtained in Fig. 11 are more sensitive to errors in time constants than the amplitude curve of Fig. 10 and, hence, can be used to determine sources of errors. It indicates that the values of corner frequencies assumed, i.e., 7.5 and 50 radians per second, are probably too low. This is particularly true for the higher corner for which, at a frequency of about 8 cycles per second, the phase shift should be 45 degrees if the network is minimum phase; if it were nonminimum phase shift, the phase shift would be even greater. A total phase shift at this frequency would then be expected to be about 130 degrees rather than the 115 degrees actually observed. Had the high-frequency corner been found at a frequency of about 15 cycles per second, the agreement would have been excellent.

This would suggest that the higher corner frequency was caused by smaller equivalent inductance in the armature circuit, i.e., the coupling of the short-circuited winding and the remainder of the armature was actually better than the indicated measurements. Further, the uncertainties in the other measurements of inductances accumulate in this time constant, as may be noted from the form of the coefficients.

Fig. 5 shows clearly that the system is essentially nonlinear because of hysteretic effects. The comments on the measurement of the field circuit time constant also show that the system is nonlinear. Hence the answers obtained must be considered approximate not only because of the uncertainty in measurement of certain time constants but also because the time constants are not actually constants.

This does not mean that the method of attack given by Dr. Burtness is unsatisfactory. Quite the contrary. At the present state, the assumption of a linear differential equation with constant coefficients is the only feasible one in a problem so complicated. However, the desirability of consideration of the effects of the nonlinearity, especially that of the main field circuit, is apparent. Suppose that this main field circuit is expressed in terms of a describing function[1] to take into account the nonlinearity. Thus, using the notation of the paper (see equation 52)

$$T_{fs}=\frac{862}{p+50}G_{N-L}$$

where G_{N-L} is a describing function which takes into account the saturation or hysteretic effect in the main field winding but does not include the effect of harmonics.

Now G_{N-L} will be a function of both frequency and the amplitude of the signal impressed on this field. Hence, it will be describable by a family of curves, with these quantities as parameters, for a given field and magnetic circuit. So the complete transfer function which takes into account some of the nonlinear effects can be obtained by combining linear and nonlinear terms.

The form of the describing function G_{N-L} has been determined[2] for systems similar to that of the amplidyne, since the combination of hysteresis and saturation approximates backlash and saturation. The linear and nonlinear functions can then be easily combined if the co-ordinates used are log amplitude and phase shift in degrees. Has the author considered this extension of his attack?

H. E. Koenig (University of Illinois, Urbana, Ill.): There are a few significant points brought out by Dr. Burtness that are worth elaborating upon. While the starting point he has chosen may appear to be a rather complex and involved one, it does give a certain sense of continuity, elegance, and completeness. In most cases, the equations can be written for the machine and its associated network in terms of the mesh-circuit variables from inspection of the graph or connection diagram. However, when encountering an unfamiliar problem, it is sometimes necessary or desirable to write the equations in terms of the branch-circuit variables and then arrive at the mesh-circuit or node system of equations by way of the transformation of variable. By following this technique one can always proceed with complete assurance. Dr. Burtness has demonstrated how this technique is applied to the analysis of the rather complex amplidyne problem.

The author has demonstrated how by means of a change in variable it is possible to take advantage of symmetry in the coefficient matrixes in reducing the complexity of the problem. Again it is important to point out that, once the simplified set of equations have been established, it is possible to attach certain physical significance to the terms in the equations. Thus, the simplified equations can be written from inspection and it is not necessary to go through the transformations as long as the problem under consideration is similar to those of past experience. However, we are interested in developing and teaching methods of analysis which will handle the unfamiliar as well as the familiar problem. In this sense I feel the work of Dr. Burtness is quite significant.

The author has considered the commutating machine as a problem in network switching. In his analysis he pointed out the important role the commutating coils play in transient operation of the machine. In the usual treatment of this problem, the machine is assumed to have an infinite number of commutator segments and zero brush width. It is clear from Dr. Burtness' paper that the true nature of the problem does not appear under these assumptions.

This paper emphasized once more the value of matrix algebra as a tool in the study of systems of linear equations. This simple tool can and should be given to the sophomore student in electrical engineering when he is first introduced to systems of linear equations in the study of network theory.

Myril B. Reed (University of Illinois, Urbana, Ill.): The problem of designing rotating machines which have certain specified properties, when incorporated into an electric network, is an important one today. In the past, machines have been built to fit traditional forms, with the electrical properties of these machines secondary, and to a considerable extent unalterable, characteristics. Now the electrical properties are the primary specifications and the machine must be built to exhibit these properties. In other words, the problem of machine synthesis is here.

The concepts of rotating fluxes, armature reactions, etc., cannot by any at present known means be designed as an integral part of a linear-lumped network, as control system design requires. However, the scheme described by Dr. Burtness presents a major step on the way toward an effective elimination of this difficulty.

The scheme of viewing rotating machinery as electric networks with mutually coupled conductors in relative motion permits inclusion of these machines into a network as an integral part rather than as an intruder. The whole of the vast amount of network analysis and synthesis is thus placed at the hand of the machine designer. Furthermore, this method of Dr. Burtness permits the effective use of one of the major design tools coming into the engineer's hands, namely, the computer.

R. W. Burtness: I am grateful for the various discussions submitted and for the interest which has been shown in this study. It might be well at this point to re-emphasize the nature of this paper. It is rather comprehensive in its approach in that it not only is an analysis of the machine itself but also leads to the synthesis of networks involving rotating machinery. It shows what can be done to enhance the understanding of complicated electric machinery by using the coupled-circuit approach and matrix algebra. Armature short-circuited turns can be considered, various impedance loads and input voltage functions can be imposed, and machine currents and voltages can be obtained. Transient response, frequency responce, and transfer functions can be obtained also. The emphasis of the paper is on the approach to the problem of electric machine analysis and system synthesis, and not on the intricacies of measurements of the constants involved.

The purpose of this paper is certainly not to list amplidyne constants. The universal means of extending into the unknown that Mr. Saunders is looking for is the method of approach itself. It is self-evident that any experimental verification is good only for the case in question. It is, therefore, necessary to concentrate on the method of approach when making an attempt to extend into the unknown, because experimental verification for every possible case becomes a physical impossibility.

It is to be expected that the age-old problems of nonlinearity and eccentricities are present. It is encouraging to note that the experimental results check as closely as they do in spite of the nonlinearity present in the saturation curve. It is certainly expected that the results would check even more closely were the amplidyne of a more recent design involving a more linear saturation curve.

Consideration of the nonlinear components in the system is possible if the variable coefficients are not transformed to constant coefficients and a point-by-point solution to the variable coefficient differential equations is attempted. This process, however, is extremely complicated and a more feasible solution to the nonlinearity of the saturation curve is that referred to by Dr. Fett. In this way, the linear and nonlinear functions can be combined and the problem is greatly simplified over the point-by-point solution.

Dr. Koenig has pointed out that it is often possible to write the mesh or, in this case, K level equations from inspection. This is certainly true. To evaluate them in terms of the individual elements, however, becomes impossible without having developed the equations originally from the element level. Thus, starting with the development on the element level produces a more complete, accurate, and workable set of equations.

As Dr. Reed has pointed out, this method of approach is the only method at present which presents a firm step in the direction of electric machine design from the standpoint of fitting a machine to a definite network problem.

Control Circuitry for Remotely Operated Electric Utility Substations

W. A. DERR
MEMBER AIEE

W. L. METZ
ASSOCIATE MEMBER AIEE

THE number of electric utility substations which are remotely operated has been rapidly increasing since 1945. Economic and system performance considerations have been responsible for the trend to centralized control and normally unattended substations.[1-4] Except where very short distances are involved, supervisory control is employed for the remote operation of electric utility substations. Supervisory control is now being used to provide centralized control for large transmission and distribution substations. Fig. 1 shows the dispatching office of the City Public Service Board of San Antonio from which more than 75 substations are controlled over privately owned line wires, circuits leased from the Telephone Company, power-line carrier channels, or microwave channels.[5-8]

When remote control is applied to a substation it is customary to have a full complement of local control equipment such as would be employed if it was to be normally attended, so that it can be operated locally for test purposes and in emergency situations when the remote-control equipment is inoperative for any reason. In the simplest type of substation involving the control of nonautomatic circuit breakers or motor-operated switches, there are no problems in applying remote control, since the local and remote control can be directly paralleled. However, when automatic reclosing circuit breakers are to be remotely operated or when circuit breakers must be automatically synchronized or tap-changing-under-load equipment operated, problems are encountered in applying remote-control equipment. The problems basically result from the fact that two points of control are involved. These problems exist if the control can be effected from two separate sets of control devices right at the substation or if the control can be effected by local control devices as well as by supervisory control or any type of direct operating remote-control system.

In this paper schemes are presented for applying remote control to circuit break-

---

Paper 55-127, recommended by the AIEE Substations Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 21, 1954; made available for printing November 24, 1954.

W. A. Derr and W. L. Metz are with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Fig. 1. Supervisory control dispatching office of City Public Service Board of San Antonio. The operation of more than 70 substations is centralized at this location

ers having various types of commercially available automatic reclosers. The problems involved when the use of automatic synchronizing or synchronism check equipment is required are discussed and typical circuit arrangements presented. Manual and automatic operation of tap-changing-under-load transformers is also discussed. Consideration is given to remote-control cutoff or transfer means. Remote lamp indications of the position of circuit breakers and disconnecting switches and telemetered indications of the quantities usually considered essential are briefly discussed.

All of the schematic diagrams presented are based on the remote-control equipment actuating relays at the substation, contacts of these relays then affecting the required operations. These actuating relays may be considered to be operated by means of supervisory control or by direct connections to remotely located control switches.

Devices Designated in Figures

1L	Circuit-breaker local control switch
	C Contact closed in close position
	T Contact closed in trip position
	O Contact closed in off position
	SC Contact closed during and after close operation and remains closed until trip operation
1L	Tap-changer local control switch
	L Contact closed in lower position
	R Contact closed in raise position
1R	Circuit-breaker remote control relays
	C Remote close relay
	T Remote trip relay
1R	Tap-changer remote control relays
	L Remote lower relay
	R Remote raise relay
25	Automatic synchronizer or synchronism check devices
25X	Auxiliary relay to energize device 25 and prepare circuit-breaker closing circuit
25Y	Synchronizing auxiliary relay
25Z	Synchronizing auxiliary relay
27L	Undervoltage relay to permit closing in the event of dead line
27B	Undervoltage relay to permit closing in the event of dead bus
43	Transfer switch ("stayput" type)
	A Contact closed in automatic position
	M Contact closed in manual position
43L	Transfer switch (spring return type)
	A Contact closed in automatic position
	M Contact closed in manual position
43R	Remote control transfer relay
	A Automatic control
	M Manual control
43X	Auxiliary transfer toggle- or latch-type relay
	A Automatic position
	M Manual position
52	Circuit breaker
	a Auxiliary switch closed when circuit breaker is closed
	aa Electric interlock closed when circuit-breaker mechanism is in closed position
	b Auxiliary switch closed when circuit breaker is open
	bb Electric interlock closed when circuit-breaker mechanism is in the open position
	LC Latch-checking switch, closed when circuit breaker mechanism linkage is relatched
	CC Circuit-breaker closing coil
	TC Circuit-breaker trip coil
	X Circuit-breaker auxiliary closing relay
	Y Circuit-breaker closing cutoff relay
57	Primary voltage adjusting element
	L Closed to lower tap position
	R Closed to raise tap position
69	Permissive control latch-type relay for automatic recloser
	A Automatic position
	L Lockout position
69R	Permissive control relay for automatic recloser
69S	Synchronizing switch
79	Automatic recloser (capacitor type)
	H Automatic recloser holding coil
	P Automatic recloser operate coil
79	Automatic recloser (motor-driven type)
	M Automatic recloser motor
	L Automatic recloser lockout
	R Automatic recloser reset
84	Tap changer
	CS Tap-changer cam switch closed on tap
	HL Time-delay heater-type relay for automatic lower operation
	HR Time-delay heater-type relay for automatic raise operation
	LLS Lower limit switch
	RLS Raise limit switch
	TL Auxiliary lower relay
	TR Auxiliary raise relay
	XL Lower control relay
	XR Raise control relay
C	Capacitor
PR	Protective relay
R	Resistor
TM1	Telemetering selection relay for circuit no. 1
TM2	Telemetering selection relay for circuit no. 2

Circuit-Breaker Control

Without Reclosing

Except for the use of cutoff or transfer switch contacts, as will be discussed later, remote-control trip and close contacts can be directly paralleled with local-control trip and close contacts as shown in Fig. 2, when no automatic features of any kind are involved. Control of such breakers can be readily effected from more than one location because the basic trip and close functions on circuit breakers are performed by momentary contacts. Any number of momentary contacts can be paralleled to effect control. Therefore, the application of remote control to nonautomatic breakers in new or existing substations presents no problems.

With Multishot Reclosing

Fig. 3 shows local control only for a circuit breaker operated by a typical motor-driven multishot recloser. The detailed internal circuitry of the automatic recloser is not shown since the operation, while different in detail for the multishot reclosers available, is similar in basic principle.

Multishot reclosers are designed to make it possible to have a predetermined number of reclosures at predetermined time settings result if a circuit breaker is

Fig. 3. Schematic diagram for a circuit breaker operated by a typical motor-driven multishot recloser with only local control

tripped by protective relay operation. They are arranged to reset to the start position if the circuit breaker remains closed on any of the automatic reclosing attempts and to travel to the lockout position if all automatic reclosures are unsuccessful. Reset can be effected after lockout if the breaker remains closed for a predetermined time interval when closed by a control switch. With reference to Fig. 3, reclosing contact *79* will close a predetermined number of times as a result of the recloser motor *79M* being energized through the complete cycle from the start to the lockout position.

Automatic recloser operation is based on circuits for its functioning being immediately established when a circuit breaker is tripped by a protective relay. When such tripping occurs the circuit-breaker control switch contacts *1LSC* and *1LO* shown in Fig. 3 remain closed and the recloser is allowed to function. The circuit breaker will be reclosed when contact *79* closes and the recloser motor *79M* will be energized through a breaker auxiliary switch contact *52b* until the lockout position is reached if no reclosures are successful. If the circuit breaker remains closed after any of the reclosures, motor *79M* is energized through breaker auxiliary switch contact *52a* until it has reset to the start position.

It is apparent from Fig. 3 that contacts *1LSC* of the circuit-breaker control switch are connected in the circuit of recloser contact *79* as well as in the circuit of the recloser motor *79M* to remove the recloser effectively from service when the circuit breaker is tripped by the control switch and to place the recloser back into service when the breaker is subsequently closed by means of the control switch. It is universal practice to employ such stayput control switch contacts in the application of all types of reclosers which are applied with only one point of manual control. It is the necessity of employing such stayput contacts to provide for proper functioning of most commercially available reclosers which makes the application of remote-control equipment to automatic reclosing circuit breakers considerably more involved than for nonautomatic circuit breakers. This is because, in general, stayput control contacts can not be paralleled and they can only be connected in series if certain operating limitations are acceptable.

When a stayput element is required in the functioning of any apparatus which can be controlled from more than one location, the control should be arranged such that a single stayput element can be controlled by momentary contacts from all control locations. All of the diagrams for remote-control operation presented are based on this fact. It is apparent that this type of operation precludes the use of stayput control switch contacts such as *1LSC* when remote control is involved.

Fig. 4 (top) and Fig. 5 (bottom). Schematic diagrams for a circuit breaker operated by a typical motor-driven multishot recloser showing methods of combining local and remote control multishot recloser. The arrangement shown provides for relay *69R* placing the recloser in and out of service at the proper time. When the circuit breaker is closed, relay *69R* is energized. If the breaker is tripped by a protective relay operation, relay *69R* remains energized to allow reclosure to be effected. If the breaker is manually tripped either locally or remotely, relay *69R* is de-energized and reclosing is prevented. Regardless of how or from where the breaker is then closed, relay *69R* is re-energized to re-establish the reclosing circuits properly. The arrangement shown in Fig. 4 is completely flexible and can readily be provided at existing as well as new substations since no control switch elements are required in addition to those employed in the customary conventional scheme where only local control is involved as shown in Fig. 3.

Fig. 5 shows a slightly different arrangement which can be employed. In this case, relay *69* is a toggle- or latch-type relay whose contacts remain in one of two positions depending on whether the *A* or the *L* coil was last energized. With reference to Fig. 5, coil *A* of relay *69* is energized when the circuit breaker is closed. If the breaker then trips from a protective relay operation, the recloser remains in service. If tripping is effected manually either by local or remote control, the *L* coil of relay *69* is energized to open the *A* contacts and close the *L* contacts. This takes the recloser out of service until the breaker is again closed. No local control switch contacts are required other than those normally needed when only local control is involved.

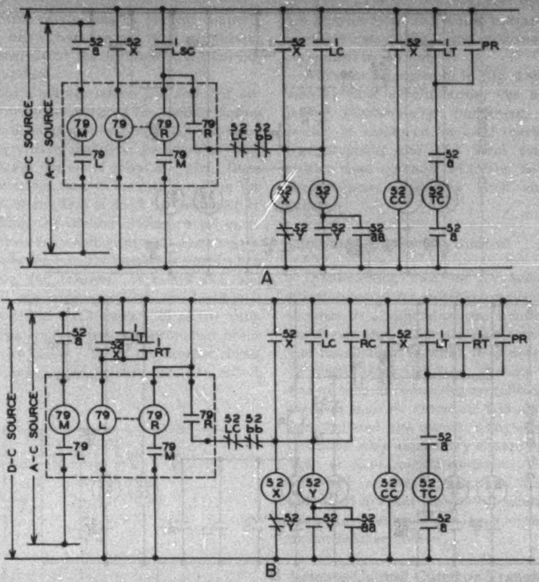

Fig. 6. Schematic diagrams for a circuit breaker operated by a motor-driven single-shot recloser

A—With only local control
B—With local and remote control

WITH SINGLE-SHOT RECLOSING

The basic circuit arrangements shown in Figs. 4 and 5, involving the use of relay *69* or *69R*, are applicable to any type of recloser. However, other arrangements not requiring the use of relay *69* or *69R* can be applied when some types of commercially available single-shot reclosers are involved.

Fig. 6(A) illustrates local control only of a breaker operated by a single-shot recloser as shown in its entirety. This recloser includes a toggle-type relay with two coils *79R* and *79L* and a motor *79M*. When coil *79R* is energized, contact *79R* closes and remains closed until coil *79L* is energized. Likewise, when coil *79L* is energized, contact *79L* closes and remains closed until coil *79R* is energized. Contact *79M* is closed after motor *79M* has been energized for an adjustable time interval.

In Fig. 6(A) a stayput contact of the control switch *1LSC* is normally employed in the reclosing circuit where only local control is involved as previously discussed. When the breaker is closed, a contact of closing relay *52X* momentarily energizes coil *79L*. This opens contact *79R* in the reclosing circuit and closes contact *79L* in the motor circuit of the recloser. If the breaker remains closed, motor-operated contact *79M* completes a circuit to coil *79R*. This results in contact *79R* closing and contact *79L* opening. The motor is thus de-energized and contact *79M* opens. If the breaker is tripped by protective relay operation subsequent to the operation just described, the breaker is immediately reclosed since contact *79R* is closed. When the reclosure is thus effected, coil *79L* is again momentarily energized by a contact of closing relay *52X*. Therefore, if the breaker immediately trips out no second reclosure can result since contact *79R* is open. If the breaker remains closed long enough for motor *79M* to close contact *79M*, the reclosing circuit is again established and subsequent automatic tripout will be followed by a single reclosure.

Fig. 6(B) is a modification of Fig. 6(A) which provides for both local and remote control of a breaker operated with the same type of single-shot recloser. Since this type of recloser contains a stayput toggle-type relay element, it is possible to eliminate any stayput contacts in the external circuitry and to employ all momentary contacts. With the arrangement shown, a circuit is completed to energize coil *79L* momentarily when the breaker is tripped locally or remotely. This results in contact *79R* being opened to prevent reclosing. The recloser otherwise functions as previously described. The arrangement shown eliminates the necessity of using relay *69* or *69R* when more than one point of control is involved. However, two separate trip contacts are required on the local control switch.

Fig. 7(A) shows local control only of a breaker operated by a single-shot recloser of the capacitor discharge type. This type of recloser contains a relay having an operating coil *79P* and a holding coil *79H*. When the breaker is closed, capacitor *C* is fully charged through resistor *R*. If the breaker is tripped by the local control switch, reclosing is prevented by the

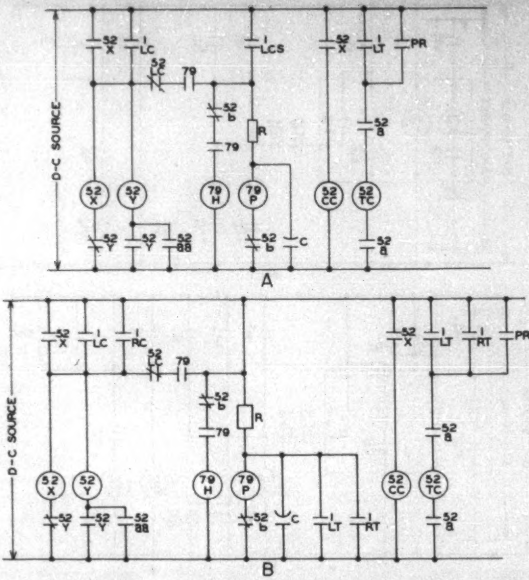

Fig. 7. Schematic diagrams for a circuit breaker operated by a capacitor discharge type of single-shot recloser

A—With only local control
B—With local and remote control

opening of stayput contact *1LSC*. If the breaker is tripped by a protective relay operation, relay *79* is operated as a result of capacitor *C* discharging through coil *79P*. Relay *79* is then held energized by its own contact completing a circuit to its holding coil *79H* through breaker auxiliary switch contact *52b* and control switch contact *1LSC*. Another contact of relay *79* completes a circuit to breaker closing relay *52X* to cause the breaker to reclose. If the breaker immediately trips, no second reclosure results since capacitor *C* cannot obtain sufficient charge to energize coil *79P* through the high resistance *R* unless the breaker remains closed for an appreciable length of time as governed by the value of resistance *R*. If the breaker remains closed long enough to charge capacitor *C* fully, a subsequent tripout will be followed by a reclosure.

Fig. 7(B) shows a modification of Fig. 7(A) which provides for both local and remote control of a breaker operated with this type of single-shot recloser. It is possible to operate this type of recloser without the use of stayput contacts on the local- or remote-control devices as shown in Fig. 7(B). Momentary contacts are used to discharge capacitor *C* when the breaker is tripped locally or remotely. This prevents reclosure when the breaker is so tripped, since relay *79* is not operated. The arrangement shown in Fig. 7(B) requires no extra relay, it being necessary only to provide two separate trip contacts on the local-control switch instead of the usual one.

With Synchronizing

Circuit breakers requiring synchronizing in normally attended stations are usually synchronized by manual means involving a synchronizing switch, synchroscope, and voltmeters. However, the closure of remotely controlled circuit breakers is frequently performed by means of an automatic synchronizer or a synchronism check device. The circuit of Fig. 8 shows a method of combining local manual synchronizing and remote automatic synchronizing where only one breaker in the station requires synchronizing prior to closing. Included in the scheme is a complete complement of automatic synchronizing equipment including the automatic synchronizer or synchronism check relay, device *25*, and the dead line and dead bus detecting relays, devices *27L* and *27B*, for closing in the event that either the line or bus is dead. The latter two devices are optional depending upon whether it is desired to have the breaker close with either the line or bus dead.

Fig. 8 shows the usual local closing circuit through the control switch *1LC* and the synchronizing switch *69S*. Remote synchronizing is initiated by relay *25X* which is energized by the remote close device *1RC*. Relay *25X* seals itself in, connects the synchronizing potentials to the synchronizer, and prepares a closing circuit to *52X* so that the synchronizing equipment can close the breaker when a condition of synchronism exists. Relay *25X* will eventually be released by the breaker auxiliary switch *52b* if the breaker closes. It can also be released by operation of the remote trip relay *1RT*. When relay *25X* releases all equipment is restored to normal.

In locally controlled substations, a common synchroscope and associated voltmeters are used regardless of the number of breakers which must be synchronized. Adequate mechanical interlocking to prevent connecting more than one set of potentials to the common synchroscope is obtained by the use of synchronizing switches with a single key for all switches. Similarly, economic considerations dictate the use of common automatic synchronizing equipment for any number of breakers in a remotely controlled substation. When more than one circuit breaker must be closed with common automatic synchronizing or synchronism check equipment, electric interlocking must be provided to insure against connecting two sets of synchronizing potentials together.

Fig. 9 shows a closing scheme for combining local manual synchronizing with remote automatic synchronizing for an unlimited number of circuit breakers in a substation. One set of synchronizing equipment consisting of an automatic synchronizer or synchronism check device and dead bus and dead line voltage relays are employed for the remote closing function. The local control follows the established practice of using separate control switches and synchronizing switches for each breaker.

In Fig. 9 relay *25Z* is normally energized through the break contact of relay *25Y*. A remote closing function for circuit breaker no. 1 is initiated by the closing of remote close contact *1RC1*. This results in energizing relay *25X1* through a make contact of relay *25Z*, a make contact of *1RC1*, and a break contact of *1RT1*. Contacts of *25X1* connect the synchronizing potentials to the dead line and dead bus voltage relays and to the synchronizing device. Another contact of relay *25X1* energizes relay *25Y* and relay *25X1* seals itself in through a make contact of relay *25Y*. The opening of the break contact of relay *25Y* in the coil circuit of relay *25Z* results in relay *25Z* releasing after a short time delay. The release time of relay *25Z* is governed by the values of capacitance and resistance connected across its coil. Release of relay *25Z* de-energizes the synchronizing start bus and prevents any other *25X* relays from being energized until relay *25X1* has released. This provides the necessary electric interlocking to prevent connecting more than one set of synchronizing potentials to the common synchronizing equipment.

Since voltage relays *27L* and *27B* are normally de-energized the breaker closing circuit must not be prepared until these relays have had time to operate. The delayed release of relay *25Z* gives these two relays time to operate if neither the bus or the line is dead by momentarily holding the breaker closing circuit open. If there is no voltage present on either the line or the bus, the breaker is closed when relay *25Z* releases. If relays *27L* and *27B* are both energized, the breaker is not closed until contact *25* of the automatic synchronizer or synchronism check device closes. When the breaker closes, the opening of breaker auxiliary switch *52b* releases relay *25Y* which in turn de-energizes relay *25X1* and restores all equipment to normal.

While the arrangement in Fig. 9 shows manual local synchronizing, the automatic synchronizing equipment can readily be employed for local operation by paralleling the *1LC* local control switch close contacts with the remote close contacts *1RC* for each circuit breaker.

Disconnecting Switch Control

Disconnecting switches for isolating transformers or for switching various bus sections in a substation are frequently motor-operated. There are remote-control installations in which it is desirable to control these switches. Remote control of such disconnecting switches is no problem since no automatic features are involved and the switch completes an operation after momentary closure of the open or close control contacts. Therefore, any number of contacts can be paralleled to effect the control similar to the arrangement shown in Fig. 2 for simple circuit-breaker control.

Remote-Control Cutoff or Transfer

The contacts of control relays which are remotely actuated can be connected directly in parallel with the contacts of local control switches as is indicated in Figs. 2 through 9. However, it is customary to provide a means of readily dis-

Fig. 9 (left). Schematic diagram combining local manual synchronizing and remote automatic synchronizing for an unlimited number of circuit breakers

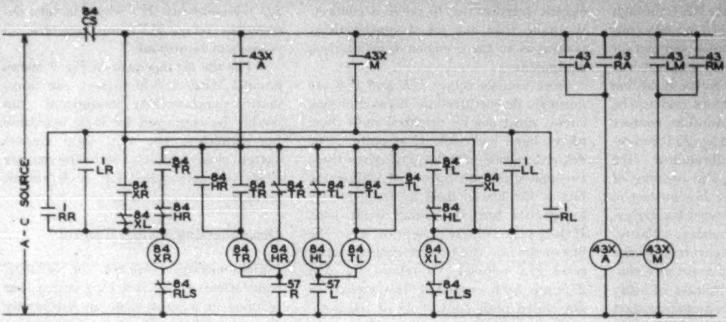

Fig. 10. Schematic diagram of tap-changer control showing local and remote manual control as well as automatic control. Arrangement shown provides for transfer between automatic and manual control being performed locally or remotely

connecting the remote-control equipment or for providing a means of transferring between remote and local control so that operations can be performed from only one or the other location. A number of different arrangements of providing such cutoff or transfer will be discussed in the following paragraphs.

REMOTE-CONTROL CUTOFF

An individual cutoff switch can be provided for each circuit breaker or disconnecting switch remotely controlled. The contacts of such cutoff switches can be connected in series with the contacts of the remotely actuated relays (contacts *1RC* and *1RT* of Fig. 2) or they may be connected in series with the coils of the remotely actuated relays. Connecting the cutoff switch contacts in series with the remotely operated relay contacts is usually preferred since inadvertent manual closure of the relay contacts cannot result in the operation of a circuit breaker or disconnecting switch. The use of individual cutoff switches makes it possible to do maintenance work on any circuit breaker or disconnecting switch without interfering with the remote operation of the rest of the substation.

A single switch can be used for the remote control cutoff of an entire station by using a single contact to open the coil circuits of all remotely operated control relays. If a single cutoff switch is employed to open the contact circuits of the remotely operated control relays, a large number of cutoff switch contacts are required for the average substation or a common remote-control bus must be involved in the remote operation of all circuit breakers or disconnecting switches. This is because it is customary to fuse each circuit-breaker control circuit individually.

When no cutoff switches are employed, local control switch contacts are sometimes used to prevent the possibility of remote closing of a circuit breaker which has been opened for maintenance purposes. This can be accomplished by connecting a *1LSC* contact of the local control switch in series with the *1RC* and *1RT* remote control contacts, as shown in Fig. 2.

CONTROL TRANSFER

An individual transfer switch for each circuit breaker or disconnecting switch can be used to transfer the control between local and remote operation by connecting contacts of the transfer switch in both the local- and remote-control circuits in series with the control contacts. This method of local-remote transfer is most frequently employed.

Individual transfer can also be effected by the use of special control switches which can be operated to a "pullout" position from the "off" position. With this arrangement remote-control circuits are established through contacts of the local control switch which are closed only in the pullout position.

If a single switch is employed to transfer the entire station between local and remote control, then both a common remote-control bus and a common local-control bus should be established. If common control busses are not employed, then a large and usually impractical number of contacts on the transfer switch are required for connecting in series with the control elements of the individual devices being controlled.

Transformer Tap-Changing Control

When manual operation only is involved in changing transformer taps under load, the remote-control contacts can be directly paralleled with the local-control contacts except for the use of cutoff or control transfer means. There are no special problems in the remote operation of such manually controlled tap changers. However, automatic control by means of a primary relay which is responsive to a change in voltage at the point where it is desired that the voltage be held constant is often involved. When a substation with such an automatic tap changer can be controlled either locally or remotely, it is desirable to arrange for transferring between automatic and manual operation both locally and remotely. It is also desirable to be able to control the tap changer manually either locally or remotely when conditions warrant manual operation. The simplest method of providing these features for a typical automatic tap changer is shown in Fig. 10.

In Fig. 10 device *43X* is a toggle- or latch-type relay which can be positioned to an automatic or manual position by momentary energization of coils *43XA* and *43XM*. As shown, these coils can be energized by spring return contacts of a local transfer switch as well as by momentary contacts of a remotely operated transfer relay. When toggle or latching relay *43X* is in the manual position, the tap changer can be controlled by either the local control switch or remotely actuated "raise" or "lower" contacts as shown in Fig. 10. These contacts can be directly paralleled since they are of the momentary type. When relay *43X* is in the automatic position, the tap changer is under the control of the automatic relays. This automatic control of the tap changer involves the operation of primary relay *57* and relays *84HR*, *84HL*, *84TR*, and *84TL*. When contact *57R* closes to initiate the raising of the voltage, heater-type relay *84HR* is energized. After a time delay, relay *84HR* closes a contact to energize relay *84TR*. Relay *84TR* seals itself in and opens the circuit to relay *84HR*. Relay *84TR* also closes a contact in the coil circuit of relay *84XR*. After a time delay, the contacts of relay *84HR* change position and this completes a circuit for energizing relay *84XR*. By means of circuits not shown the closing of the make contacts of relay *84XR* results in operation of the tap-changer mechanism to the next higher tap. The control circuits are arranged so that relay *84XR* must be energized only momentarily to have the mechanism complete a tap change. Opening of cam switch *84CS* while the tap-changing equipment is between taps results in relay *84TR* being de-energized. This restores all equipment to normal. An automatic lowering function is performed in a similar manner by closing primary relay contact *57L*.

If it is desired to have means provided to locally cutoff remote control and transfer functions, an arrangement as shown in Fig. 11 can be employed. This scheme is based on the use of a 3-position local transfer switch. With this switch in the manual position, the tap changer can be raised or lowered locally by means of the local-control switch contacts *1LR* and *1LL*. With this switch in the automatic position, the tap changer is under the control of the primary relay as previously described. With this switch in the remote position, the type of operation effected is dependent on the position of toggle- or latching-type transfer relay *43X*. With relay *43X* in the manual position, the tap-changer position can only be changed by the remotely actuated contacts *1RR* and *1RL*. With relay *43X* in the automatic position, the tap changer is under the control of the primary relay.

Remote Lamp Indication

With any remote-control system employed for the operation of circuit breakers and disconnecting switches, provisions must be made for lamp indications of the position of these devices at the remote-controlling location. When direct wire control is employed for short distances, the remote lamp indications are usually provided by direct connection to auxiliary switch contacts on the circuit breakers or disconnecting switches. In the case of supervisory control, the auxiliary switch contacts are connected to relays which are an integral part of the supervisory control system.

The use of only an *a* or a *b* auxiliary switch on a circuit breaker to provide both the red and the green lamp indications through supervisory control equipment is usually considered adequate. It is apparent that such an arrangement gives entirely accurate information except for the possibility of a broken wire to the auxiliary switch or failure of the auxiliary switch to make contact. For either of these conditions, an incorrect indication results. When the possibility of such a failure cannot be tolerated, both *a* and *b* breaker auxiliary switches can be used to provide the remote indications. When this is done, the remote indications can be made to function exactly the same as local lamp indications. If there is a broken wire to the auxiliary switches or if an auxiliary switch fails to make contact, both the remote red and green lamps are simultaneously extinguished or lighted. This latter arrangement requires somewhat more equipment than the simple arrangement based on the use of either an *a* or a *b* auxiliary switch contact.

It is customary always to use both an *a* and a *b* auxiliary switch for the remote indication of the position of a disconnecting switch. This is because a motor-operated switch can stop in an intermediate position and the use of only an *a* or a *b* auxiliary switch contact would give incorrect information if the disconnecting switch stopped in other than the extreme open or closed position. The breaker and disconnecting switch auxiliary switch contacts which are used for remote indications are usually entirely separate from those which are used for local switchboard lamp indications.

In addition to lamp indications of the position of the devices remotely controlled, it is customary to provide lamp indications of remote-control cutoff or transfer switches and various alarm conditions necessary for most efficient operation of the station. If a single remote-control cutoff or transfer switch is employed for the entire station, a single contact of the switch can be used to provide a remote lamp indication. If individual cutoff or transfer switches are provided for each device controlled, it is customary to furnish a single remote indication for reasons of economy. The intelligence for the indication is obtained by the use of a series circuit involving a contact of each cutoff or transfer switch. The contacts used in the series circuit must all be of the same type and should be closed in the "remote" position of the cutoff or transfer switch. This makes it possible to provide indication that all switches are in the remote position or that one or more switches are not in the remote position.

Following is a list of some alarm conditions which it is sometimes desirable to have reported to the controlling location.

1. High transformer temperature.
2. Low transformer oil level.
3. Low air pressure for pneumatically operated circuit breakers.
4. Tap-changer off-tap indication.
5. Low station battery voltage.
6. Faulty pilot wires for pilot-wire relaying.
7. Bus differential-relay operation.
8. Transformer differential-relay operation.

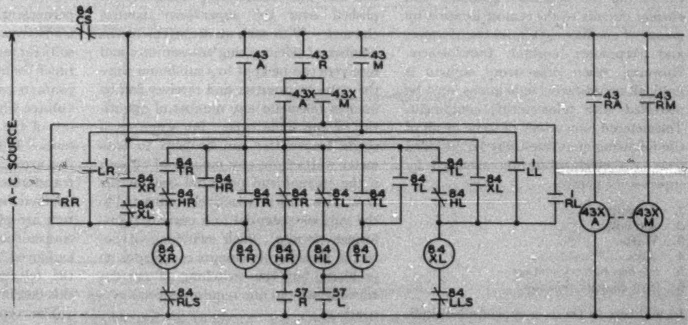

Fig. 11. Schematic diagram of tap-changer control with local transfer switch to choose between remote operation, automatic operation, or local manual operation

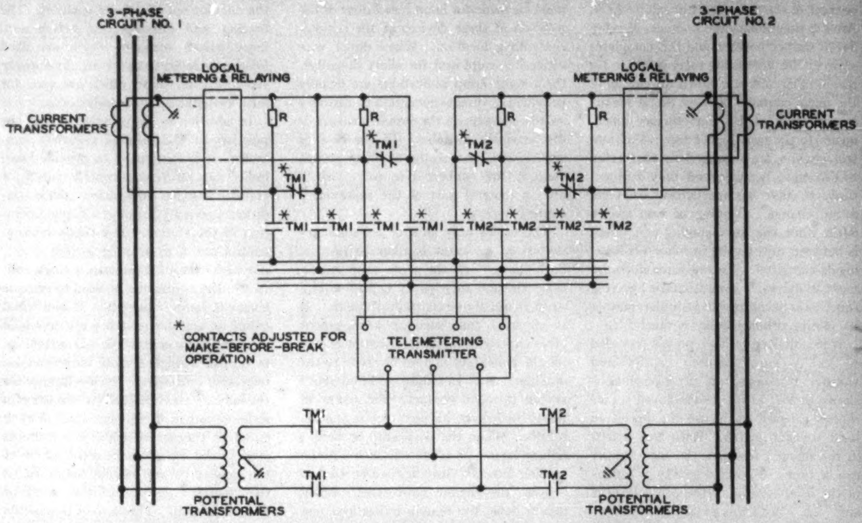

Fig. 12. Schematic diagram showing a method of selectively switching current and potential circuits to a watt-telemetering transmitter

A single alarm contact must be used for the remote indication of each such condition which it is deemed desirable to have reported to the controlling station. It is often acceptable to group alarm contacts for a common remote indication for reasons of economy.

Telemetering

Some quantitative indications are desirable for the operation of most remotely operated substations. When direct wire control is employed over short distances, the necessary quantitative information can sometimes be obtained by connecting the necessary potential and current circuits to the remote location by means of auxiliary potential transformers and step-down current transformers. However, when supervisory control is used, all quantitative indications must be provided with telemetering equipment. Telemetered indications of some or all of the following quantities may be provided from a typical substation operated by supervisory control.

1. A-c amperes.
2. A-c volts.
3. Watts.
4. Vars.
5. Station battery voltage.
6. Tap-changer position.

In addition to these, a synchronism indication must be provided if remote manual synchronizing is employed rather than automatic synchronizing as previously discussed.

To provide continuous indications of all desired quantities from a remotely operated substation requires individual channels and individual telemetering systems for each indication. Economic considerations usually preclude the furnishing of continuous telemetered indications from a remotely operated substation. Instead, it is customary to provide for selective or "on-call" telemetered indications, with the selective function being performed by the supervisory control and the telemetering being accomplished over the supervisory control channel. With such an arrangement the number of telemetering transmitters and receivers can be kept to a minimum since the same transmitter and receiver can be used to telemeter any number of quantities of the same type. For example, a single transmitter can be used to telemeter watts from any number of circuits if the current and potential coils of the transmitter can be selectively connected to the various potential and current transformer circuits. Such switching of potential transformer circuits constitutes no problem, but the switching of current transformer circuits requires special precautions.

Relays with reliable make-before-break contact adjustments must be employed for the switching of current transformer secondary circuits. Additional safeguards against the possible opening of a current transformer circuit are sometimes provided. One such additional safeguard consists of the use of auxiliary transformers in each circuit which saturate at a relatively low ohmic burden and prevent excessive voltages from appearing even if there is a failure in the make-before-break adjustment of the selective relays. Film cutouts are sometimes connected across the contacts of the switching relay. These film cutouts are chosen so that they will break down and permanently short-circuit the current transformer circuit if an open circuit results for any reason. Resistors are sometimes connected across the selective relay contacts as shown in Fig. 12 to limit the voltage which can result if there is a failure of the make-before-break relay contacts. It is apparent from Fig. 12 that this arrangement does not allow all of the transformer current to pass through the telemetering transmitter since the resistors are effectively in parallel with the transmitter. When this arrangement is employed, the design and calibration of the telemetering equipment must take this fact into consideration.

The type of telemetering equipment

employed for selective telemetering from a remotely controlled substation is governed primarily by the type of channel provided for the supervisory control. When a metallic circuit is employed, telemetering equipment whose operation is based on the circulation of a small value of direct current over the interconnecting circuit can be used. Economies in the cost of telemetering equipment can be realized when such d-c systems are used. When the supervisory control operates over a leased or privately owned telegraphic-type channel as can be obtained with telephone-line carrier, power-line carrier, or microwave equipment, the telemetering equipment must be of the pulse rate or pulse duration type.[9-11] Most of the commercially available telemetering equipment of the pulse or frequency type can usually be employed for operation over such channels.

Conclusions

The control and position indication of circuit breakers is usually the primary function of any system for the remote operation of electric utility substations. When no automatic equipment of any kind is involved in the operation of the circuit breakers, the application of remote-control equipment is simple. When automatic reclosers of any type are involved, the application becomes somewhat more complex. This is primarily because the design of commercially available reclosers is based on the use of stayput contacts in the reclosing circuit. Since stayput contacts cannot be connected in series or in parallel if a satisfactory control circuit is to result, the usual reclosing circuits must be modified when a substation is remotely operated.

Typical schematic diagrams have been presented diagrams involving the use of a number of different types of automatic reclosers. All of the schemes presented have no operational limitations since a circuit breaker can be tripped from either location and closed from the other location. The principles of operation indicated in the diagrams are applicable to automatic reclosing arrangements other than those shown.

The circuitry for circuit-breaker control becomes more involved when closing can only be effected through automatic synchronizing or synchronism check equipment, since economics dictate the use of a common set of such equipment regardless of the number of circuit breakers involved.

While circuit-breaker operation and indication is the primary function which must be performed in a remotely operated substation, individual applications may involve disconnecting switch operation and tap-changer control. In addition, various alarm functions are often provided for and telemetered indications of important electrical quantities are frequently desirable.

Discussion

S. S. Watkins (Gibbs & Hill, Inc., New York, N. Y.): The paper is a valuable contribution to the literature of electric control, because of its clear presentation of the fundamental principles that affect control problems. It will be especially useful to the engineer who must design the control of substations to satisfy operating and maintenance requirements, using commercially available equipment with a minimum of special features.

While the circuits for local and remote control of automatic reclosing are valuable in themselves as circuits for specific equipment, they have an additional value in the fundamental treatment of momentary and stayput contacts and the problems presented when more than one point of control is used. Similar methods of analysis should apply to local and remote control of the automatic starting equipment for rectifiers, motor generator sets, and hydroelectric generators.

Under "Remote Control Cutoff or Transfer" the paper mentions that it is possible to use a contact that closes in the pullout position of the local control switch, in series

Fig. 13 (left) and Fig. 14 (right). Supervisory control circuits with the contacts of the remotely operated control relays so that the switch must be in the pullout position before remote control can be effected. Since the control switch can be placed in the pullout position only by going through the trip position, we would not usually consider this a satisfactory operating arrangement. However, this section is valuable for reviewing the different possible arrangements. Since the type of control transfer is closely related to the methods of system operation and maintenance, this subject deserves early discussion with the engineer who will operate the system.

In the discussion of supervisory control circuits under "Remote Lamp Indication," it is gratifying to note that the authors recognize a weakness in the practice of using only a single *a* or *b* auxiliary switch for both the red and the green lamp indications of circuit-breaker position. In my own organization we specify that each change of indication of a red or green indicating lamp on the control-station panel shall be initiated only by an energized circuit through an auxiliary contact of the supervised apparatus, and that loss of supervision current from any piece of supervised apparatus shall cause both lamps to be dark and shall cause the usual alarm signals to sound in the control station.

This specification for reliable indication of circuit-breaker position can be satisfied by either of the circuits shown in Figs. 13 and 14. Each circuit is in actual use and each uses three wires from the circuit breaker to the supervisory control panel. In Fig. 13 a single supervision wire is energized positive or negative for the two positions. In Fig. 14 separate red-lamp and green-lamp wires are energized positive for the respective positions. I suggest the use of Fig. 14 as a desirable standard circuit for the following reasons:

1. The standard circuit has some similarity to lamp circuits that are commonly used in local control.
2. It avoids the permanent connection of any coil to positive polarity, which, under some conditions, has caused deterioration of insulation.
3. It avoids the possibility of short-circuiting positive and negative busses in case of faulty adjustment of auxiliary switches.

W. M. Moody (Gibbs & Hill, Inc., New York, N. Y.): The authors are to be congratulated for their extensive coverage of the circuitry of remote control. My comments apply to the application problems of remote synchronizing. The authors cover quite adequately a system of interlocks to prevent connecting two sets of synchronizing potential together. Interlocks are obviously desirable, but they do not solve all the problems of remote synchronizing.

Automatic synchronizers are surprisingly accurate when they are adjusted to perform one function under a given set of conditions; but when they are required to perform two or more widely different functions, special provisions are required to obtain a comparable degree of accuracy, or careful consideration is needed to determine that the error introduced is acceptable. One of the most obvious problems is encountered where breakers of different voltage, vintage, or manufacture have appreciably different closing times. Accurate synchronizing requires that breaker closing be initiated several degrees ahead of synchronism so that by the time the breaker contacts close the voltages will be in phase. The error introduced by different closing times is usually tolerable and can be minimized by setting midway between the two closing times and by holding the allowable frequency difference to a low value; in extreme cases an auxiliary timing relay may be used to add delay to the fast-closing breaker.

More serious error is introduced when common equipment is used for different functions such as synchronizing and synchronism check. Automatic synchronizers are not synchronism check relays and will not initiate closing unless a frequency difference exists across the breaker. However, synchronizers are frequently supplemented with a time-delay voltage relay so that the two operating together will function as a synchronism check relay. The objection to this arrangement is that the setting of the synchronizer must usually be modified to accept a static phase angle and the error introduced may not be tolerable. As an example, consider the two following simplified conditions:

A transmission loop open at one end will have a static phase angle across the open breaker due to reactive drops around the loop. This angle may be as much as 30 degrees or even more, but a study of the system will usually show that the breaker can be closed without serious shock to the system or damage to equipment. If, however, closing is to be initiated by the synchronizer and voltage relay, it will be necessary to set the synchronizer to accept the static angle of, say, 30 degrees.

If now this same synchronizer is to be used for synchronizing two machines or two systems, the setting used to accept the static angle will cause an equal synchronizing error, i.e., will cause the machines to be paralleled when they are 30 degrees out of synchronism. An error this large may be sufficient to stress the generator shaft or the stator windings beyond their design limits if the system impedance is low enough or it may be sufficient to cause system instability.

To avoid situations of this nature, it is standard practice of my company to specify a synchronism check relay if the system is such that synchronism can be established over two or more circuits. The separate devices are then adjusted without compromise to perform the function for which they are intended.

Automatic synchronizers will not initiate closing if the voltage magnitudes are vastly different, but they will accept a greater difference than is generally desirable. The angular error introduced in synchronizing is usually tolerable, but large reactive surges may result. For this reason some type of voltage telemetering is usually desirable so that the dispatcher may determine that voltages are within limits before initiating synchronizing. Some type of slip-frequency telemetering is also a common requirement so that the dispatcher can determine whether the incoming machine or station is fast or slow and approximately how much.

Although remote synchronizing has several problems, the solutions to the problems are straightforward and the end result is more accurate synchronizing than is usually obtained by manual means. Experience has shown that automatic synchronizing within 1 or 2 degrees can be obtained within a reasonable test time. I should like to make two suggestions for testing automatic synchronizers:

1. A phase shifter with slip rings can be rotated at low speed to operate as a frequency changer and thereby give a constant slip frequency. Such a source is more easily manipulated, is faster, and is more accurate than using a large generator, and does not interfere with normal operation.
2. A 2-pen high-speed recorder is more accurate than a synchroscope for testing the synchronizer settings and gives a permanent record of the performances. One pen should be connected across the breaker contacts to show the instant of closure; the other should be connected to receive the difference voltage (equivalent to voltage across the breaker). The two pens together show the voltage across the breaker at the instant the contacts close, and by proper adjustment of the synchronizer the breaker will close when the voltage is zero.

W. A. Derr and W. L. Metz: We are extremely grateful for the excellent discussions of Mr. Watkins and Mr. Moody. Each of these discussions has amplified important considerations involved in the design of remotely operated electric utility substations, and are therefore valuable additions to our presentation.

Comments on the remote control cutoff arrangement employing contacts of the local control switches are given in the third paragraph of Mr. Watkins' discussion. He has inferred that the local control switch mentioned in our paper could only be placed in the pullout position by going through the trip position as must be done with standard breaker control switches. The control switch which we briefly described would be arranged so that it could only be placed in the pullout position from the off position. Therefore, the remote control could be cutoff or placed back in service regardless of the position of the breaker.

We are in complete accord with the other comments and description given by Mr. Watkins as well as with Mr. Moody's discussion of remote synchronizing.

Operation of Turbine Generators During Off-Peak High Power-Factor Periods—Practices of One Utility in a Metropolitan Area

W. J. ROBERTS
NONMEMBER AIEE

R. L. WEBB
FELLOW AIEE

BEFORE the beginning of World War II, the Consolidated Edison 60-cycle system operated with the load distributed mainly from the generating station busses with relatively low-capacity intermediate-voltage tie feeders interconnecting the major stations from north to south. The largest of the several interstation ties was rated about 40 megavolt-amperes (mva). Some operated at 13 kv and some at 27 kv.

In general, the load power factors of that time, measured at the generating station bus, varied from 0.83 to 0.85 during the day load and dropped to 0.78 to 0.80 during the early morning hours of off-peak load operation. These loads were carried with generator terminal power factors (pf) varying from 0.80 minimum during the day to 0.75 during off-peak operation. Capacitive loading consisted of the 13-kv and 27-kv distribution feeder cables plus a small amount of 4-kv distribution feeder capacitors.

Since the beginning of World War II, the 60-cycle system has experienced a peak load increase of 61 per cent with a corresponding increase of 65 per cent in generating capacity and has been equipped with a double-circuit high-voltage (138-kv) tie-feeder system between the north and south ends of the area served. In addition, one new generating station has been built to supply power directly into this tie-feeder network. Area substations supplied from the high-voltage circuits have been constructed to supply medium-voltage distribution systems direct from the 138-kv circuits.

The new 138-kv system circuits are made up of pressure-pipe type and oil-filled cable feeders. These, including the older 138-kv cables between Westchester County and the Hell Gate Generating Station, have added a total of approximately 295 capacitive megavars (mvar) to the system load at normal voltage. Also, the installation of unswitched capacitors on the 4-kv distribution part of the system have added an additional 85 mvar.

All of this increase in capacitive load has been very helpful in assisting to supply the load and system equipment demand for mvar during the high-load period of the day but it has caused the early morning light load pf of the system to increase to approximately 0.97 lagging. As the system develops, it is anticipated that the early morning load pf will soon be slightly leading.

To complicate further this over-all problem of light load operation, the generators installed during the early 1930's were 1,800 rpm units having short-circuit ratios of approximately 1.0, while since World War II, the new units have generally been 3,600 rpm machines with short-circuit ratios varying from 0.9 to 0.7, and the outlook to the future is for even lower short-circuit ratios at maximum turbine capabilities.

It is the object of this paper to review the nature of the problems associated with the foregoing trends, system loads, and generator characteristics from an operating engineer's viewpoint. The method of approaching a solution to the situation on this particular system is described herein.

System and Loads

A simplified diagram of the present 60-cycle system is shown in Fig. 1. It gives the connected generating capacity at each station and indicates the major distributing points, wherever they may be, at the generator bus or at the area substation. It shows also the day-load operating conditions and associated bus pf. In this case, the summer load conditions are given since load pf are lower at this time of the year because of the effects of rather heavy air-conditioning demands in the city. The diagram shows the medium-voltage tie circuits between the generating stations which remain unchanged, while the high-voltage circuits form a new low-impedance tie from one end of the system to the other. Voltage and angle regulators are used in the medium-voltage tie feeders to control reactive and power flow respectively between the generating stations.

Fig. 2 shows the same simplified diagram, giving typical connected generation, station loads, and bus power factors for system conditions experienced during the early morning hours when the light load of the 60-cycle system is approximately 700 megawatts (mw). In this case, a day in April was chosen since air-conditioning loading is small at that time of the year.

As already pointed out, Figs. 1 and 2 show that the 138-kv cable circuits, whose one-way distance between Hudson Avenue Station and Dunwoodie Substation is approximately 34 miles plus the 8 miles of single-circuit cable to Sherman Creek, add approximately 295 capacitive mvars to the system. Though this is quite acceptable and, in fact, beneficial during the day-load period shown in Fig. 1, it increases the average pf of the system during the off-peak morning hours to approximately 97 per cent lagging. Since it is impracticable to keep all generators operating at the system average pf, some machines operate at unity, or slightly leading, while others operate at a pf somewhat below the average, depending upon bus voltage requirements.

Considering that system development plans now in progress call for the addition of approximately 18 miles, 70 mvar of 138-kv cable circuits and that the unswitched capacitor additions to the system during the next 5 years could be approximately 75 to 100 mvar, it is expected, with the normal load increase during that same period, that the early morning hour average generator pf will become leading.

Limits of Generator Operation

Since about 4 years ago when the last large complement of high-voltage cable was added to the system, there has been some concern about the possibility that unstable operation of the system generators during the early morning may result in case certain contingencies should occur which require relatively large load pickups by the machines then in service. Since the transient stability of generators is

---

Paper 55-120, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31-February 4, 1955. Manuscript submitted October 21, 1954; made available for printing December 7, 1954.

W. J. ROBERTS and R. L. WEBB are with the Consolidated Edison Company, New York, N. Y.

little affected by operating pf, the steady-state stability of the machines was determined for the most severe type of system disturbance which could reasonably be expected, with a sizable factor of safety added to it. It has been concluded, after a study of the various possibilities, that the greatest probable loss of capacity which may be expected at that hour of the morning would interrupt approximately 200-mw flow into the system. This would occur if one generator at Astoria Station is tripped automatically or if the Niagara-Mohawk tie feeders are interrupted while supplying their rated capacity into the northern end of the system. The possibility of additional capacity disconnections which might conceivably occur at the time of trouble in one element of the system, should there be an incorrect operation by one of the protective relays, is not considered in these assumed losses.

The minimum spinning capacity on the system in the early morning hours is approximately 1,000 mw. Since the maximum generator loss is estimated to be approximately 200 mw, with some possible additional loss being a possibility, this figure was increased by an arbitrary 50 per cent to allow for this additional contingency plus the differences in turbine governor performance which will result in some variation in the percentage of the load pickup by the different machines. The resulting 300-mw load change is approximately 30 per cent of the mva rating of the remaining generators on the system, or about 35 per cent of the mw rating of the same units.

In view of the aforementioned operating condition and to understand the approach made in the calculations described in the Appendix, it should be mentioned at this point that none of the generators on this closely knit system are at present supplied with high-speed excitation response equipment. A few of the recently installed units and one of the older machines are equipped with automatic voltage regulation of the motor-operated rheostat type to provide operating convenience or to improve machine stability where the short-circuit ratio of the unit is below 0.75 at maximum turbine rating. Accordingly, the stability calculations have been based upon the steady-state operating conditions only.

Since the objective of this investigation was to provide curves which would show limits of permissible operation for the system generators, it was desired to provide characteristics covering the entire range of operation from early morning light load conditions to the normal day peak load machine capability. The several generator operating limits which came under close study in this investigation are:

1. Field excitation. The excitation limits are determined by exciter capability, temperature rise in the main generator field winding at the operating hydrogen pressure, and mechanical stresses imposed on the field winding resulting from expansion and contraction forces caused by temperature variations with changes in machine loading.

2. Stator thermal capability. The stator winding temperature limit was taken as that specified by the manufacturer for the different hydrogen pressures at which the machine may be operated. The latest recommendations for resistance temperature detector indications, at all permissible hydrogen pressures, were used.

3. End-turn area heating. Heating of the metal structures in the end-turn area of the machine because of high-leakage flux which occurs when operating at high or leading pf was discussed with the respective manufacturers, and their recommendations were worked into over-all machine capability curves to avoid exceeding maximum recommended temperatures in the structural and support members at this point.

4. Steady-state pullout. The steady-state pullout loading in mw for the initial operating condition of each generator, with the imposition of the system contingency assumed, was determined by calculation over the entire operating range of the machine. A sample calculation of the type used is presented in the Appendix.

5. Loss-of-field relays. It is the practice of the authors' company to use reverse reactive current relays for generator loss-of-field protection. It becomes necessary, therefore, to limit the amount of reverse reactive kilovolt-amperes which the generators may carry, particularly at light and heavy mw loadings.

Results of Stability Calculations—Machine Thermal Limits

Curve *A-A* of Fig. 3 shows the calculated initial loading of a generator which would allow the assumed increment of load to be picked up by that machine, immediately following the assumed system contingency, without the generator becoming unstable electrically even though no change was made in the operating field current. As the initial load on the generator is increased, a point is reached beyond which the turbine cannot pick up an additional 30 per cent of its mva rating. From this point on, the new stability criterion, namely, field strength or internal voltage sufficient to carry full turbine output stably gives a new curve shown in Fig. 3 as *B-B*. Since the stability limit

of most generators determined in this way allows considerably more leading kilovolt-amperes to be carried than is practically necessary with present-day system loads, an additional safety margin was applied which amounts to approximately 20 per cent of the generator mva rating. This results in a new curve shown in Fig. 3 as *C-C;* see the Appendix.

It will be noted that the lower end of this curve is cut off at approximately 44 mvar leading. This is done to prevent the reverse reactive current loss-of-field relays from closing their contacts. Though the operation of this relay alone would not cause tripping of the generator, the development of a bus voltage dip causing an undervoltage relay to operate would disconnect the machine from the system. This loss-of-field relay limitation allows the generator to carry approximately 67 per cent of the loss-of-field relay setting, which is usually 35 to 40 per cent of generator mva rating. Data of these types were determined for all system generators and have been issued to the operating department for guidance in operating each machine.

Fig. 4 shows a typical characteristic giving the generator thermal limits as determined by maximum field current, stator or ampere capabilities, and permissible mvar as limited by leakage flux in the end-turn area, when operating underexcited. Care should be taken to find out whether the field current limits are determined by winding temperature or by mechanical stresses in the winding created by the forces of expansion and contraction working against the tendency for the winding to be held stationary because of high centrifugal forces. The stator winding current limit is specified by the manufacturer. He may find this limit to be determined for long machines by expansion and contraction effects rather than by actual temperature, when operating at the higher hydrogen pressures. The end-turn metal temperatures caused by leakage flux are best determined and recommended by the machine manufacturer.

Operating Experience

Curves of the type described herein have been in use as a guide to the station operators for about 5 years. They are still being used on this basis. The curves of Fig. 5 duplicate the stability limit curves of Fig. 3 for a number of generators on the system which customarily operate through the early morning hours of the day. The operating points for these machines taken during the early hours of the day are plotted beside the recommended operating characteristic. It will be noted that, in some cases, the operating experience with the system as it is today indicates that the normal operation of the machines is coming close to the characteristic determined and described in this paper.

It is anticipated, therefore, that some of the safety margin which was taken in the construction of curve *C-C* in Fig. 3 must soon be given up as the cable system is increased and the installed unswitched capacitors are increased in total mvar during the next few years. It will, of course, be possible to move curve *C-C* even farther into the leading direction should a decision be reached to install fast-acting

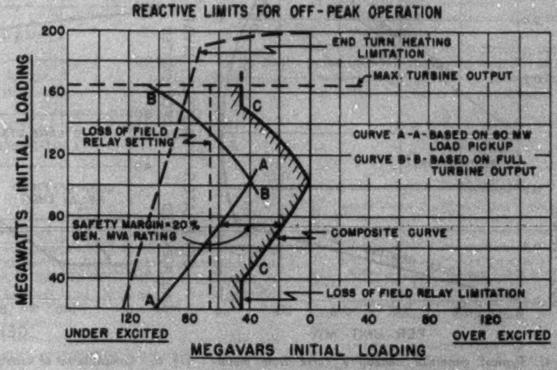

Fig. 3. Curves showing results of generator mvar capability calculations

regulators on those machines which usually operate during the early hours of the day. These machines would, of course, be those which form the most efficient combination in the several stations.

Operating Curves

Fig. 6 presents an actual set of curves used for one of the larger machines to maintain stable operating conditions during the early part of the day. The different sections of each curve may be identified to show how the limits determined and plotted in Fig. 3 are applied in the operating instructions for that particular machine, as a guide to the control room operator in loading that unit.

Conclusions

1. Turbogenerators can be successfully operated at high or slightly leading pf if operating personnel are provided with guides pointing out limits which should properly be observed. One means of doing this is described in this paper.

2. The limits of permissible minimum generator field currents can be lowered with the installation of fast-response excitation-control equipment.

3. With the application of reasonable safety factors, suitable generator steady-stability limits can easily be established for a wide range of operating conditions.

4. The use of reverse reactive current loss-of-field relays provides a means for automatically disconnecting a generator from the system, before loss of synchronism, in case minimum field current limits should not be maintained in the machine.

or

$$E_d = P_m\left(\frac{X_d+X_e}{E_s}\right) \qquad (1)$$

Also

$$E_d = E_b + jIX_d = E_b + I\,(\cos\theta - j\sin\theta)jX_d$$

$$E_d = [(E_b + IX_d\sin\theta)^2 + (IX_d\cos\theta)^2]^{1/2}$$

but

$$P = E_bI\cos\theta, \text{ and } Q = E_bI\sin\theta$$

Substituting

$$E_d = [(E_b + QX_d/E_b)^2 + (PX_d/E_b)^2]^{1/2} \qquad (2)$$

Solving for Q

$$Q = \frac{[E_d^2 - (PX_d/E_b)^2]^{1/2} - E_b}{X_d/E_b}$$

or

$$Q = \left[\left(\frac{E_dE_b}{X_d}\right)^2 - (P)^2\right]^{1/2} - E_b^2/X_d \qquad (3)$$

Substituting for E_d its value in equation 1

$$Q = \left\{\left[\left(\frac{E_b}{E_s}\right)\left(\frac{X_d+X_e}{X_d}\right)P_m\right]^2 - P^2\right\}^{1/2} - E_b^2/X_d$$

When $E_b = 1$ pu

$$Q = \left\{\left[\left(\frac{X_d+X_e}{X_d}\right)(P_m/E_s)\right]^2 - P^2\right)^{1/2} - 1/X_d \qquad (4)$$

Curve *B-B* shown in Fig. 3 may be obtained from the foregoing equation either by graphical construction or by substituting values of P and solving for Q since all other quantities are known. In either case, curve *B-B* gives the limiting initial mvar for a given initial mw load, based on picking up full turbine output P_m.

When the recognized maximum contingency will result in a load pickup of 0.3 pu, the pull out power P_m should equal the initial load P plus the expected pickup of 0.3 (of generator rating).

$$P_m' = (P + \Delta P) = \frac{E_dE_s}{X_d + X_e}$$

or

$$E_d = \left(\frac{X_d+X_e}{E_s}\right)(P + \Delta P) \qquad (5)$$

where

$$\Delta P = 0.3\,\frac{\text{generator mva}}{\text{base mva}}$$

Substituting this value for E_d in equation 3

$$Q = \left\{\left[\left(\frac{X_d+X_e}{X_d}\right)(P+\Delta P)E_b/E_s\right]^2 - P^2\right\}^{1/2} - E_b^2/X_d$$

When $E_b = 1$ pu

$$Q = \left\{\left[\left(\frac{X_d+X_e}{X_d}\right)\left(\frac{P+\Delta P}{E_s}\right)\right]^2 - P^2\right\}^{1/2} - 1/X_d \qquad (6)$$

It will be found more convenient to work with equation 6 in the form given than to reduce it further. The reduction in bus voltage which takes place when load is picked up will reduce the initial load. To avoid further complication, and since the 0.3 load pickup is a rough estimate, this reduction in initial load was considered an added safety margin.

When values of P are substituted in equation 6, values of Q are obtained for plotting curve *A-A*. This curve gives the limiting initial mvar which can be carried by the generator with an initial mw load and safely pick up an increment of load equal to 0.3 of its mva rating.

To apply the foregoing to a practical case, this example will use generator 7 at Hudson Avenue Station. This is an air-cooled single-shaft 200-mva 0.8-pf 16.5-kv generator connected to a 27.6-kv bus through a 16.5/27.6-kv autotransformer. The short-circuit ratio on 200 mva, 16.5-kv is 1.00. The autotransformer reactance is 2.5 per cent on a 100-mva base. The reactance from the bus to the equivalent system generator based on calculating board studies is 18 per cent on the same base. Expressing all reactances in pu on a common 100-mva base

$$X_d = \frac{1}{1.00}\left(\frac{100}{200}\right) + 0.025 = 0.525$$

$$X_e = 0.18$$

Substituting in equation 4, for a bus voltage of 27.6 kv (1 pu) and a maximum turbine capability of 165 mw

$$Q = \left\{\left[\left(\frac{0.525+0.18}{0.525}\right)\left(\frac{1.65}{1.21}\right)\right]^2 - P^2\right\}^{1/2} - \frac{1}{0.525}$$

$$= [3.37 - P^2]^{1/2} - 1.90$$

The value of 1.21 for E_s is the calculated voltage behind synchronous reactance for the off-peak load on the equivalent system generator. For a loosely connected system, the determination of E_s will require experience and judgment. By calculating Q for $P = 1.0$, 1.2, 1.4, and 1.6, curve *B-B* is obtained.

Similarly, when known values are substituted, equation 6 becomes

$$Q = [1.24(P + 0.6)^2 - P^2]^{1/2} - 1.90$$

By calculating Q for $P = 0$, 0.4, 0.8, and 1.2 curve *A-A* of Fig. 3 is obtained.

The intersection of curves *A-A* and *B-B* is a point whose mw value is equal to the maximum turbine capability less the assumed load pickup of 30 per cent of the generator mva rating. Above this mw value, the turbine can no longer pick up a load equal to 30 per cent of rating and the criterion of stability becomes full turbine output.

Also shown in Fig. 3 are the manufacturer's end-turn heating limits, modified for the autotransformer reactive losses. The loss-of-field relay setting for this generator is 66 mvar. This setting is a function of transient stability, breaker tripping time, and available taps on the relay.[1] To prevent reaching the relay setting value, 67 per cent of the setting has been selected as the limit for operation.

To the calculated stability limits has been added an arbitrary safety factor equal to 20 per cent of the generator mva rating, to be plotted along the mvar scale so as to move the curve in the overexcited direction. No safety margins were added to the end-turn heating limits supplied by the manufacturers. For this generator, the end-turn heating does not constitute a limit in the underexcited region. The composite curve *C-C* is shown in Fig. 3 in heavy lines. It is composed of portions of the two stability limit curves referred to in the foregoing and the loss-of-field relay limit.

The schematic circuit shown in Fig. 7 may be reduced to the simplified circuit. Because of normal variations in load distribution and pf, it was considered sufficiently accurate to use $(X_d + X_e)$ for the transfer impedance and to neglect the effect of the nearly unity pf loads.

Using the simpler criterion of an infinite bus,[2] the calculated stability limits will be somewhat on the underexcited, or optimistic, side of curves *A-A* and *B-B* of Fig. 3 for the example given. To avoid confusion, the infinite bus limits are not shown.

Discussion

Raymond S. Watts (Commonwealth Edison Company, Chicago, Ill.): As with other companies, the Commonwealth Edison Company finds the highest pf at night and on week ends when the load is at a minimum. Week ends when there is a 3-day holiday such as the Fourth of July and Labor Day of the past year are particularly troublesome.

On these long week ends, the total system load reached a minimum of 800,000 kw, approximately one-quarter of the system peak, with a total capacity running of 1,800,000 kw of large efficient units which it is not desirable to shut down.

Previous to last year it was the practice at these periods to switch out several large high-voltage cables, set the timing device on the switched capacitors so that they would be disconnected, and operate rotary-type condensors absorbing the maximum of vars. This enabled us to keep generators at slightly lagging pf. Even when these steps were taken, the voltage remained higher than normal. In recent years, 17 large generators have been equipped with modern voltage regulators and, for the first time, switched capacitors were left on their normal cycle over these holiday week ends. Generators were allowed to go slightly leading in pf, absorbing vars from the system.

For instance, a unit at Crawford Station absorbed 10 mvar with an output of 10 mw. A unit at Fisk and one at Calumet with 78 and 40 mw respectively, absorbed as much as 5 to 10 mvar and several other units running at the time had 0 vars or unity pf. No trouble of any kind was experienced.

Safe limits of leading pf with varying loads have been determined and the machines are always operated well within these values. At such times it is the practice and the intent to have all the voltage regulators in service that system conditions will permit.

H. O. Simmons, Jr., and **C. A. Woodrow** (General Electric Company, Schenectady, N. Y.): For a specific system, Mr. Roberts and Mr. Webb have clearly evaluated an important concept: the determination of generator kilowatt-kilovar loading guides designed to give successful system performance under planned emergency conditions. As they indicate, for a metropolitan system with relatively short electrical distance between generator and load and with a number of ties between stations, the use of generator voltage regulators can be avoided by the adoption of suitable generator loading guides based solely on steady-state stability considerations. However, as the authors also indicate, this solution becomes more and more difficult as the system growth includes more kilovar generation out in the system and less and less kilovar output from the generating station itself.

The authors conclude: "The limits of permissible minimum generator field currents can be lowered with the installation of fast-response excitation control equipment." The principal purpose of this discussion is to further evaluate this conclusion, taking into consideration two additional important trends in metropolitan system growth.

These trends are:

1. New generating stations are necessarily more remote from the load area and the average electrical distance from generator to load is continually increasing.
2. Power flows to the load area through a limited number of heavily loaded channels and the loss of any one channel can create a sudden increase in the electrical distance between generator and load.

Fig. 8 illustrates conditions which may be more severe than any of those evaluated by the authors but which are readily possible, i.e., an external system having 30-per-cent system reactance (based on maximum turbine rating) as viewed from the generator terminals. Fig. 8(A) shows initial operating limits without voltage regulators, with zero kilovar safety margin, and on the somewhat dangerous assumption that the generator terminal voltage will never be less than rated voltage. Curves *A-A* and *B-B* are based essentially on the quite logical assumptions used by Mr. Roberts and Mr. Webb. No turbine will be called upon to increase suddenly its output by more than 30 per cent of rating (curve *A-A*); above 70 per cent of initial turbine output, the maximum turbine incremental demand is the difference between turbine rating and the initial turbine output (curve *B-B*). As indicated, the most critical condition develops at around 70-per-cent turbine output. Here kilovar output cannot safely be reduced below 0.3 pu. This, we feel, would be unduly restrictive for many systems.

Fig. 8(A) also illustrates another limit, curve *C-C*, which becomes significant when the loss of a channel of power flow increases the external system reactance—in this illustration, from an initial value of 30 per cent to a final value of 50 per cent. At constant excitation (no regulators), this change in reactance causes a drop in generator voltage and introduces a significant steady-state stability limitation, even though there is no increase in turbine output. As indicated, the initial limit required to prepare for this emergency is exactly the same as curve *B-B* at 0.87 pu power. At higher loads, this new reactance change limit, curve *C-C*, becomes limiting and supersedes the dotted portion of the *B-B* curve. Of course, if the system design is such that the change in reactance is 10 per cent rather than 20 per cent, then this operating limit slides appreciably to the left, perhaps slightly into the underexcited region at maximum turbine rating rather than 0.25 pu overexcited.

Most users would find it highly undesirable to accept such operating restrictions as are indicated by Fig. 8(A), and Fig. 8(B) is included to indicate the influence of adding voltage regulators to this system. The reactance change limit, curve *C-C*, disappears and curves *A-A* and *B-B* become essentially one straight line with acceptable underexcited kilovars of 0.5 pu at maximum turbine rating and considerably more underexcited kilovars at lower turbine output. Such drastic underexcitation is seldom required and, therefore, ample margin normally exists for reducing the generator voltage by 5 per cent under system light load conditions. To all intents and purposes, steady-state stability limits have disappeared. Other considerations such as generator end-turn heating and the selection of suitable loss-of-excitation protection become governing.

On the system of Fig. 8, 30-per-cent initial reactance and a maximum of 50-per-cent final reactance, transient stability problems should not develop if modern high-speed relaying and circuit breakers are used. However, installations have been made and others are contemplated where this final reactance is considerably greater than 50 per cent. In these cases, transient stability can become a limitation even with the most modern generator voltage regulations and switchgear. Kilowatt-kilovar generator operating guides can become necessary, particularly where the planned schedule includes some reduction in generator terminal voltage during system light load conditions.

A—Without voltage regulator
B—With voltage regulator

W. J. Roberts and R. L. Webb: It is interesting to note that the experiences in Chicago, as described by Mr. Watts, are essentially the same as those in the New York City area. In fact, his early morning load level has about the same percentage characteristic with respect to the peak load level, as experienced in New York. There is little doubt that the generators which operate during the off-peak periods on the New York system will also require the addition of fast-acting voltage regulators as is now the case in Chicago.

Mr. Simmons and Mr. Woodrow have done a good job of showing the actual benefits of fast-acting voltage regulators applied to the operating characteristics of the generator referred to in the paper. We are, of course, pleased to know that they agree with the approach and assumptions used by us and we agree with them in regard to the future possibilities of voltage regulating equipment as the capacitance loading on the system increases.

Detection of Grounds in Generator Field Windings

L. L. FOUNTAIN
FELLOW AIEE

THE TREMENDOUS increase in the size of individual generating units in recent years has spurred the interest of operating engineers in at least two respects; first, because it means knowing more about the limitations and capabilities of the generator itself and, second, because of the available protective relays that will prevent the machine from exceeding its capabilities and incurring the risk of damage. There has been in the past a division of opinion among operators in their philosophy concerning keeping generators in service when some risk is involved. There are a number of different types of abnormal conditions that can occur in a generator without affecting its ability to generate kilowatts, but that do involve some risk of severe damage if the machine is kept in service. This risk is usually contingent on the slow development of the abnormal condition into a serious one or the occurrence of a second abnormality. Many operators have followed the philosophy that a generator should be kept in service to supply power to the ultimate consumer until an outage can be scheduled even though some weakness which might eventually lead to severe damage is known to exist in the machine. This practice has been influenced by shortages in reserve capacity to the extent that loss of a unit meant inadequate capacity to supply the load.

The diversification of reserve capacity by interconnections among several systems and a general increase in the amount of reserve capacity have altered this situation substantially, and it is now possible to remove a unit from service without jeopardizing the system. This reduces the necessity of assuming risks of damage to a machine to maintain service. The capital investment in a large modern generating unit is also a deciding factor. As a result, there is a greater tendency to operate generators without exceeding their capabilities, and to repair minor abnormalities as soon as they are discovered, even though a forced outage is necessary to do so. To accomplish this, the maximum capabilities must be known, and suitable instruments and protective devices must be available to detect abnormalities.

An excellent example of the recognition of a limitation of generating units is the development of a standard stating the ability of a unit to withstand an unbalanced external short circuit and the development of the generator negative-sequence current relay.[1-3] It was known that negative-sequence current in the armature of a generator would cause localized heating in the rotor structure, which if allowed to continue would cause a severe rotor failure. However, it was not until recently that the industry was able to establish a standard that relates the magnitude of armature negative-sequence current to the permissible time it can flow without causing damage. Relay engineers were then able to design a relay that permits the generator to carry its full capability in terms of negative-sequence current and then removes the generator from service to prevent damage. While this new relay is not yet widely applied, operators who are installing it are planning to connect it to trip the unit when the capability point is reached.

General Considerations of Generator Protection

Protective-relaying schemes have been developed to detect substantially all types of faults and abnormalities that might exist in generators. Schemes to detect internal faults usually take the form of some type of differential protection with parallel winding, or split-phase protection is used in some cases. Separate ground-fault relays are used where the minimum ground-fault current is below the sensitivity of the differential protection, and these relays may also operate for external faults. Some form of backup protection can be used to protect the machine against prolonged system faults.

Many specialized relays are available to detect specific abnormalities such as negative-sequence current, loss of field, motoring, out-of-step operation, single-phase operation, overspeed, overvoltage, excessive vibration, bearing insulation failure, etc. Application principles for all of these devices are discussed in the technical literature in more or less detail. In 1951, the Committee on Relays published a report[4] which included the results of a questionnaire on practices in the protection of a-c generators, and specific recommendations for modern protective schemes.

Generator Field Ground Detector

One facet of a-c generator protection that has not received sufficient study concerns detecting grounds in the field windings. There are many schemes available and in use for this purpose, and all of them have some weakness or shortcoming. The following discussion directs attention to the difficulties of detecting grounds in the field windings, and recommendations for effective protective measures are developed. The cylindrical-rotor type of generator is given primary consideration in the following, but the same statements and conclusions apply in some degree to salient-pole machines.

Paper 55-125, recommended by the AIEE Relays Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 21, 1954; made available for printing December 6, 1954.

The authors acknowledge the work of M. J. Brown, Westinghouse Electric Corporation, in developing the nonlinear resistor scheme.

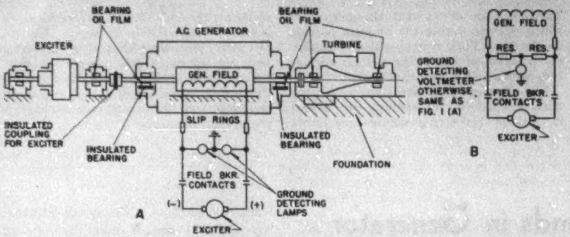

Fig. 1. A—Typical bearing arrangement on a modern a-c generator and turbine together with the field circuit equipped with lamps as a means of detecting grounds. B—Generator field circuit equipped with a voltmeter for detecting grounds; otherwise it is the same as in A

The Relay Committee report[4] makes the following statements concerning grounds on the field circuit of machines and ground detectors: "A ground on the field circuit is not serious in itself, but it indicates the presence of weakened insulation or mechanical failure, and serious damage may result if a second ground should occur. A simple form of ground indication consists of two lamps in series connected across the rotor winding with their mid-point grounded. This scheme of ground detection gives positive indication only for faults near the terminals of the field winding. More sensitive ground indication can be obtained by replacing the lamps with resistors and connecting the mid-point to ground through a sensitive relay. Complete coverage can be obtained in all cases by the use of a separate a-c supply with a low-voltage transformer. One terminal of the transformer secondary winding is connected to the field winding, while the other terminal is connected to ground through a sensitive relay." See Figs. 1 and 2.

Actually, as is developed later, none of these forms of ground indication can be considered as giving positive indication of a ground at any location in the field winding, and the use of a separate a-c supply involves some risk of further damage to the generating unit.

In the summary of replies to the questionnaire, the Relay Committee reported the following: "Thirty-five per cent provide no means for detecting a grounded field winding; 25 per cent depend on d-c ground lamps for indicating a grounded field [Fig. 1]; 15 per cent use some form of d-c voltmeter scheme; 13 per cent use both ground lamps and voltmeter; 12 per cent use an a-c relay with a transformer source [Fig. 2]." While this analysis shows considerable variation in practice, apparently 65 per cent of the operators are using some form of generator field ground detection.

The Problem

There are two factors that make the detection of generator field grounds difficult. First, the field circuit is normally isolated from ground, and even with constant voltage applied, the potential between the conductor and the rotor iron is variable, depending on the specific location in the winding. Under normal conditions, the capacitance to ground of the field winding forces a distribution of voltage so that the potential between each slip ring and the rotor iron is one-half of the applied voltage, and the potential to iron at the electrical center of the field winding is zero.

The second factor is found in the bearings of the machine. The generator designer provides insulation in both bearing pedestals so that a path for the flow of shaft current through the bearing pedestals and the bedplate does not exist. The reason for this is to prevent the damaging effect that current, even though very small, can have on the bearing surfaces. The turbine bedplate is generally a part of the station ground, and its bearing pedestals are available to connect the bedplate to the shaft electrically. Unfortunately, this connection is a poor one, because the bearing contains an oil film that can be an insulating barrier for low voltages and provides a path of low and variable conductivity at higher voltages. The conducting qualities of the bearing-oil film depend greatly on the quality and purity of the oil, clean oil being a poorer conductor than oil containing dirt or moisture.

Thus, one can conclude that the shaft and rotor of a turbine generator may be electrically isolated from the bedplate and station ground by the insulating properties of the bearing-oil film. At best, the path available to connect these parts electrically is one of questionable but probably poor conducting ability. Unfortunately, no factual data are available to indicate the magnitude of voltage that must be applied to an actual bearing-oil film to cause positive breakdown or to indicate the range of conductivities that might be encountered in practice. Both of these characteristics are highly variable and depend on many factors, including the thickness of the oil film, the area of the bearing surfaces, and the condition of the oil. Data on new clean oil are available however.

The lamps, voltmeters, or relays used to detect field-winding grounds are normally connected between the slip-ring brushes and the station ground. Even with the field winding solidly connected to the rotor iron, operation of the ground detector is dependent on the circuit between the shaft and the station ground, which includes the bearing-oil film. It is for this reason that the ability of these ground-indicating schemes to detect field-winding grounds is open to question.

Ground Detection Schemes

To show more specifically how these factors affect the operation of different schemes used to detect rotor grounds, a brief discussion is given of the principles on which the schemes are based.

LAMP AND VOLTMETER SCHEMES

The lamp and voltmeter schemes, which are the most widely used, are simple and easily understood. A typical example of each is illustrated in Fig. 1, but there are a number of variations that have been used.

The lamp scheme of Fig. 1(A) operates on the principle that the voltage to ground of each field lead is the same, and the voltages applied to the two lamps are equal. Under these circumstances, the lamps glow with equal brightness, but the brightness is a function of the excitation voltage applied to the generator field. With modern generator voltage regula-

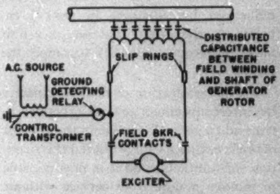

Fig. 2. Generator field circuit equipped with a-c ground relay and showing capacitance of field winding to shaft. Bearing arrangement the same as shown in Fig. 1(A)

tors, there can be considerable aperiodic variation in excitation voltage and consequently in the lamp brightness.

If the conductivity of the bearing-oil film is assumed to be excellent, and to form a good connection between the shaft and station ground, a ground at either terminal of the field winding will cause one lamp to be short-circuited and extinguished while the other lamp glows with greater brightness. It is then possible for the operator to determine that a ground has occurred and which terminal is grounded. A ground at the center of the field winding will not disturb the voltages to ground at the lamp location, and the ground is not indicated. For grounds at other locations in the winding, the degree of voltage disturbance and the probability of ground indication is between these two extremes.

On the other hand, if the oil film is assumed to be a poor conductor, insulating the shaft and rotor from the station ground, a ground at any point in the field winding will not be indicated by the lamps. The lamps in series across the excitation voltage divide the voltage equally and continue glowing with the same intensity.

The voltmeter scheme of Fig. 1(B) operates on the same principle as the lamp scheme. Under normal conditions, the voltage between the mid-point of the two resistors and ground is zero and is so indicated by the voltmeter. A ground at either terminal of the field winding causes the voltmeter to indicate a voltage equal to one-half of the excitation voltage, subject, of course, to the conductivity of the bearing-oil film. Like the lamp scheme, no indication is given of a ground at the center of the field winding.

From this brief and elementary discussion it is obvious that the lamp and voltmeter schemes are subject to ground location and bearing-oil film conductivity, and when all of the probabilities are combined, the effectiveness of the schemes is seriously in doubt.

ALTERNATING-VOLTAGE METHOD

The alternating-voltage method, one variation of which is shown in Fig. 2, was developed several years ago and is based on the principle of raising the entire field circuit to some potential above ground so that a ground at any point in the field winding can be detected. Alternating current was chosen because it is conveniently available and can be transformed to the proper magnitude. The alternating voltage is applied to one terminal of the field winding. The voltage to ground at the opposite field terminal is the sum of the alternating voltage and the d-c excitation voltage, so that part of the ground insulation is stressed at a higher crest potential than normal. A sensitive a-c relay in series with the alternating-voltage source is relied upon to indicate the ground fault.

This scheme overcomes the problem of detecting a ground at the center of the field winding, but it is still subject to failure to indicate because of poor conductivity in the bearing-oil film. In addition, the alternating-voltage method introduces a serious operating hazard that cannot be ignored. The field winding of a turbine generator has considerable capacitance to ground. The capacitance to ground of the field winding of a typical average-sized turbine generator is of the order of 0.3 to 0.7 microfarads. Again, if the bearing-oil film is assumed to be a good conductor, an alternating voltage applied to the winding-to-ground capacitance will establish a capacitive current to ground that must flow through the bearing. The bearing designer will not permit any current in the bearing because of the danger of pitting and subsequent failure.

At this point, two conflicting requirements become apparent. First, if no current is to be permitted in the bearing, the magnitude of the applied alternating voltage must be small enough that the bearing-oil film remains an insulator and prevents the flow of current. Second, if the ground detector is to operate at all, the alternating voltage must be high enough to cause conduction through the oil film when a rotor ground occurs. The variations encountered in the conducting properties of the oil film are too great to permit the choice of a voltage that meets both of these conditions. In view of the possibility of damage to the generator bearings, the alternating voltage method should be avoided as a ground detector.

DIRECT-VOLTAGE METHOD

A scheme similar to the alternating voltage scheme in Fig. 2 except for the use of a direct voltage has also been employed. The relay, of course, is then a sensitive d-c relay. This scheme eliminates the danger of bearing damage, because the direct voltage does not establish the flow of any current. There is an improvement over the lamp and voltmeter schemes of Fig. 1 as the entire field winding is at an elevated potential with respect to ground, and a fault at any point will cause a change in voltage to ground.

The detector relay still depends on conductivity in the bearing-oil film to pass sufficient current to cause operation. The principle objection is in the fact that one side of the field winding operates at a higher-than-normal voltage to ground, overstressing the ground insulation.

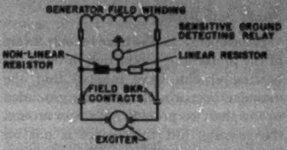

Fig. 3. Generator field circuit equipped with a nonlinear resistance bridge and a sensitive d-c relay for detecting grounds. This scheme has no null points as long as exciter voltage varies over a small range due to regulator action. Bearing arrangement the same as shown in Fig. 1(A)

NONLINEAR RESISTOR SCHEME

A variation of the voltmeter scheme of Fig. 1(B) is the d-c relay scheme shown in Fig. 3. Two resistors, one of which has constant resistance while the other is a nonlinear resistance that varies with applied voltage, are connected in series across the field winding. A sensitive d-c relay of the galvanometer type is connected from the mid-point of the resistors to ground and is the ground-detecting element.

The use of one nonlinear resistor provides a means of detecting a ground at any location in the field winding. As the resistance of the nonlinear resistor changes the location of the point in the field winding where the voltage to ground is zero also changes. Thus, the voltage to ground at all points in the winding is variable, depending on the applied excitation voltage, and a ground at any point will eventually disturb the voltages and circulate a current.

The nonlinear resistor can be replaced by a rheostat or a series of fixed resistors with pushbuttons to vary the resistance between the field leads and the relay tap. The operator must periodically move the rheostat or depress the pushbutton to move the point of zero voltage to ground in the field winding. A nonlinear resistor makes it unnecessary for the operator to take any action.

As is true with the other schemes discussed, this scheme is also dependent on the conductivity of the bearing-oil film. It does provide a means of detecting grounds at any location in the winding without applying additional voltage to overstress the ground insulation. This scheme therefore has advantages over those previously discussed.

Shaft Slip Rings

Some operators who have become aware of the problem of conduction through the bearing-oil film have insisted that the manufacturer provide a slip ring grounded to the shaft to provide a by-pass around the bearing, but this device is not an answer to the problem. The only time the brush riding on this slip ring is called upon to carry current is when a ground occurs in the field winding. Even at this time, the voltage applied to the brush is small.

The performance of brushes that normally carry no current is notoriously unpredictable. A film having good insulating properties is apt to develop on the slip ring, so that no current will flow from the slip ring to the brush unless sufficient voltage is applied to cause breakdown of the film and conduction. Thus, the slip ring in parallel with the bearing-oil film is a poor by-pass device, and it is possible that the bearing-oil film may have higher conductivity than the slip ring. If this is the existing condition, the slip ring is ineffective and by-passes none of, or only part of, the current from the bearing.

In addition to the conduction problem, the generator designer has a serious problem in finding a location to place the shaft slip-ring and brush assembly. Space on a turbine generator shaft is at a premium and considerable additional expense may be involved in adding the slip ring. For these reasons, the ability of a shaft slip ring to perform its intended function is questionable, and the expense is apt to be far greater than warranted by the advantage gained. The shaft slip ring is not a recommended solution to the problem.

Summary

All of the ground detector schemes now in use have a common shortcoming in that they depend on conductivity through the bearing-oil film to start operation. No scheme offers a positive solution to the problem. The lamp and voltmeter schemes will not operate for grounds at or near the center of the field winding because the voltage distribution is not sufficiently disturbed. The alternating-voltage method introduces a hazard because capacitive current may flow through the bearing and cause damage. The direct-voltage method eliminates this hazard but retains the objectionable feature of overstressing some of the ground insulation at a higher-than-normal voltage. The nonlinear resistor scheme enables detection of a ground at any point in the winding, but depends on the bearing-oil film conductivity for operation. The use of a shaft slip ring is not a solution to the problem, because the film on the ring surface can prevent conduction and, at best, only a portion of the current is removed from the bearing.

Experience with these schemes has been varied. Some operations have been reported, but whether the detector indicated a ground at the instant it occurred is always debatable. It is conceivable that a field-winding ground might exist for days or weeks before the bearing-oil film conductivity becomes high enough to permit operation of the ground detector. It is also conceivable that the detector might never operate. In any event, it is extremely important that operators realize that the lack of a ground detector indication does not necessarily mean that there is no ground on the winding. The ground detector must be treated as a device that may indicate a ground, but some more positive means must be used to detect grounds.

Periodic testing of the insulation with the machine at rest is one test that is frequently carried out but this is not necessarily conclusive. It is possible that a ground in the field winding will disappear as the centrifugal forces due to rotation get less and less. Therefore, some positive check should be made while the machine is still running near normal speed. This can be accomplished by momentarily by-passing the bearing-oil film and pedestal insulation with a jumper from the shaft to ground. A portable instrument or the normal ground relay protective equipment can be used to indicate whether a ground exists.

Conclusions

1. All ground detector schemes now available and in use rely on the conduction of current through the bearing-oil film for effective detection of grounds. The bearing-oil film has variable insulating properties depending on the quality and cleanliness of the oil, and in many cases it may prevent the detector from performing its function.

2. The use of a shaft slip ring to by-pass the bearing-oil film is not recommended. Because of the glaze or film that will develop on the surface of the slip ring, the bearing-oil film is apt to be more conducting, in which case, the purpose of the shaft slip ring is defeated. In addition, the expense and difficulty of finding a location on the shaft for the slip ring and brush assembly are not justified by the questionable advantage gained.

3. The alternating-voltage method is not recommended because of the danger of establishing capacitive leakage current through the generator bearings. This current can be established even though no field ground exists. Also, part of the ground insulation is overstressed because of the a-c component of voltage added to the normal exciter voltage.

4. Even when the alternating voltage is rectified into a direct voltage, the condition of overstressing the field insulation continues to exist.

5. The scheme, shown in Fig. 3, which seems to offer the best over-all protection is that using a voltage divider bridge with one leg of the bridge a non-linear resistor which will shift the zero point of ground measurement as the exciter voltage varies under regulator control.

6. In the final analysis the insulation resistance of the winding should be determined or some overvoltage means should be used to determine the insulation condition at every shutdown period of the generating equipment, in order to insure that no undetected grounds in the field winding exist.

7. Movement of the rotor coils due to rotational forces may contribute to establishing a field-winding ground. Therefore, an insulation check with the machine running at normal speed is desirable. The bearing-oil film and pedestal insulation should be by-passed with a jumper during this test.

Discussion

H. C. Barnes (American Gas and Electric Service Corporation, New York, N. Y.): In presenting this summation of the methods of field ground detection and the problems associated with each, the authors have rendered a valuable service to utility engineering and operating personnel.

At the start of the paper, the case is argued in favor of more protection to trip a unit. This is based on the increased reserve capacity making it more permissible and the increased cost making it more desirable. This is generally true but it should be remembered that, while the system is growing rapidly, the individual unit is taking tremendous jumps in size. A 250-megavolt-ampere unit, now a common item, or a 350-megavolt-ampere unit, now in actual production, could represent a good percentage of an area's generation even though the over-all system was large enough to justify such units. Its loss could create serious local problems. The huge shafts, shells, and other parts of these large machines may present stress problems from unequal cooling or heating after a tripout, particularly with temperatures of 1,200 degrees now a reality, and higher ones no doubt on the way. Aside from these factors, there is no return on the investment when a machine is not producing, having been unnecessarily removed from service.

These comments are of no value if it is assumed that these devices trip only when there is actual trouble. However, it is irrefutable that tripping devices and associated wiring can fail or be wrong because of mechanical or electrical surges and that test men make mistakes. Therefore, false tripping is bound to occur. If an infinite number of trip devices were applied, a trip signal would conceivably be constantly present. Therefore, the need should be carefully weighed before connecting additional devices to trip. Where tripping is necessary, such as for an electrical short circuit, fast tripping should certainly occur. If a time delay is permissible, even though slight, it may eliminate trips from surges or transients even though still subject to its own or the test man's failure. If there is enough time for the operator to analyze the difficulty, then an alarm should be sufficient, particularly if supervisory personnel is readily available for consultation. Even the addition of alarms should be carefully considered since they can become so multitudinous that they are confusing.

As for field protection, generators installed on the A. G. & E. system since about 1945 have been provided with the a-c rectifier-type relay connected to alarm. These have been supplemented to d-c voltmeters with suitable test transfer switches. So far, no grounds have been experienced. There have been a few false alarms. Also, several maintenance men have discovered that the ground detector relays should have been removed from service before starting to work on the brushes. Field temperature recorders are standard, as they have been since even before the ground detectors. These indicate short-circuited turns, since they become erratic under this condition, especially if the short circuit is intermittent, as it often is on a rotating field. There have been two cases of short-circuited turns.

The most recent case of false indication was not from the relay contacts but from the indicating lamp which is part of the relay. It was noted that the lamp brilliancy was varying. Test voltmeters between the slip ring and ground indicated a voltage varying in magnitude and polarity. A voltmeter reading between the shaft at an exposed point at the turbine end of the generator gave voltages of −55, −25, +30, and +28 for the low- and high-pressure generators of two, 200-megavolt-ampere cross-compound units. They persisted even with the relay removed from service. When the shafts were grounded through a low resistance, this voltage disappeared and the lamp on the relay became normal. Apparently a capacitance charge was building up on the shaft until it was high enough to break down the oil film. This was remedied by completion of installation of shaft grounding which was provided for bearing and gear protection. Whether the glaze due to no current as mentioned in the paper will nullify this is yet to be determined. Such glaze has caused difficulty with the field temperature recorders.

Despite our rather negative experience, the field ground problem is considered serious enough to justify continued use of detection equipment supplemented by in- and out-of-service testing. The relay will continue to be connected to alarm.

H. T. Seeley and **E. J. Burdick** (General Electric Company, Schenectady, N. Y.): Throughout this paper the authors have discussed the subject of detection of generator field-winding ground faults with an overly pessimistic viewpoint, leaving the impression that the generator rotors are not and cannot be effectively grounded; that all detector schemes must therefore operate through the bearing-oil film; and that the a-c and d-c ground detection schemes overstress the field-winding ground insulation. We do not share these views but believe that automatic detection of field circuit ground faults should be used and that effective detection of these faults is available with present-day equipments.

In conclusion 1 the authors state that all ground detector schemes now available and in use rely on the conduction of current through the bearing-oil film for effective detection of grounds. No mention is made of hydro turbine-generators whose rotors are effectively grounded by the turbine without depending upon conduction of current through the bearing-oil film; nor was mention made of various resistance grounding paths located in the turbine on steam turbine units. These paths do not depend upon conduction of current through the bearing-oil film. We have found, by calculation and measurements of units in service, that water-sealing glands or carbon-packing glands effectively ground the turbine and generator rotors. If these grounding paths do not exist, the rotor can be grounded by other means.

We agree wholeheartedly with the authors' recommendation that users should measure the sensitivity of their protection rather than simply taking for granted the grounding of the generator rotors, as otherwise disappointments may occur. Such a measurement is easily made in connection with the d-c field ground detector relay and should be made a routine periodic test wherever there is any doubt as to the effectiveness of the rotor grounding path.

In the discussion of the alternating- and direct-voltage schemes of detection, the authors mention the objection that one side of the field winding operates at higher-than-normal voltage to ground, overstressing the ground insulation. It should be pointed out that the American Standards Association standards require that the field winding be given a high-potential test at 10 times rated voltage.[1] The field-winding insulation is also capable of operating continuously at a ceiling voltage of 120 per cent of rated. This higher insulation margin available in the field winding has made it possible to design a ground detection scheme that does not overstress the ground insulation.

The authors have concluded that the voltage divider bridge with one leg of the bridge being a nonlinear resistor, offers the best over-all protection. Yet this scheme relies on changes in the exciter voltage to give complete protection to the field winding. With this system, a ground fault conceivably could exist for a long period without being detected if the generator were base-loaded.

The direct-voltage scheme does not suffer the disadvantage of relying on changes in exciter voltage, since it has its own power supply and can detect field ground faults without depending on the excitation voltage. The d-c field ground detector relay, with which there have been years of successful experience, offers the best solution available today.

1. ROTATING ELECTRICAL MACHINERY. *ASA C50-1943*, American Standards Association, New York, N. Y., Mar. 29, 1943.

J. E. Barkle, C. C. Sterrett, and **L. L. Fountain:** Mr. Barnes' description of the experience of the American Gas and Electric Service Corporation is of considerable interest to the authors. There was no intention in the paper itself to imply a recommendation that generator-rotor ground detectors be used to trip the machine off the line in the event of operation. In fact, the authors would agree that this is a form of relay protection that can and probably should be installed to sound an alarm and provide an opportunity for the station operator to analyze the trouble.

The philosophy Mr. Barnes proposes is a wise one to follow in any relay situation. A relay should not be connected to trip unless it is used to detect trouble that requires immediate removal of the equipment from service, and there is reasonable assurance that incorrect operations of the relay are a remote possibility. A generator-rotor ground in itself is not serious, but is undesirable. The danger lies in the occurrence of a second ground in the field winding which could cause serious damage.

Mr. Barnes also describes sporadic operation of an indicating lamp in a ground detector scheme on one of the American Gas and Electric units. This was eventually traced to the fact that the generator shaft was not grounded. When provision was made to ground the generator shaft, the shaft voltages disappeared and the lamp operation was normal.

Mr. Seeley and Mr. Burdick express favoritism for the direct-voltage method of detecting field grounds. There is no question in the authors' minds that this scheme offers a workable solution to the problem, but it is our opinion that the objections to it are sufficient to make its use undesirable. The discussers point out that the American Standards Association standards require that the field winding of a generator be given a high potential test at 10 times rated voltage and that the field-winding insulation is capable of operating continuously at a ceiling voltage of 120 per cent of rated voltage (see reference 1 of Mr. Seeley's discussion). Obviously, these requirements are designed to produce considerable insulation margin in the generator rotor.

Under normal conditions, with 250 volts applied to a 250-volt field winding, the capacitance to the rotor iron will force a distribution of voltage such that the potential at each field terminal is one-half the applied voltage. Therefore, the voltage between each slip ring and the shaft would be 125 volts. On the assumption that the d-c ground detector voltage is 125 volts, a distribution of voltage is forced so that the potential between one of the slip rings and the shaft is raised to 375 volts. This means that the insulation at this terminal of the field winding is stressed at approximately three times the normal value. While this is not sufficient to cause breakdown of the insulation, it appreciably reduces the insulation margin.

It should also be pointed out that on machine field windings rated at 375 volts, the American Standards Association standards require an overpotential test of 3,750 volts. Using the direct-voltage method of rotor-ground detection can apply a voltage to the winding insulation in a 250-volt machine that is equal to, or higher than, that normally existing in a 375-volt machine.

These discussers do not agree that the generator-rotor can be insulated from ground by the bearing-oil film but Mr. Barnes appears to substantiate the fact that this can occur by describing an actual case. There is no question that the rotor can be grounded by various auxiliary devices, but the value and desirability of these is questioned. The use of shaft slip rings was discussed in the paper and the authors do not feel that this is a reliable method of grounding. Design and manufacturing difficulties are usually encountered in attempting to provide a means for grounding the shaft.

The voltage divider bridge method described in the paper has been designed to provide ground detection equal to that of the direct-voltage method, and it does not have the disadvantage of applying higher-than-normal voltage to the rotor insulation. It seems logical to take the stand that higher-than-normal voltage should not be applied to insulation when it is not necessary to do so. In the case of a base-loaded machine where the field voltage remains constant for a considerable length of time, an artificial change in the resistance of the nonlinear resistor can be produced by having a pushbutton connected to short-circuit a portion of this resistance.

In summary, a general conclusion of the paper is that all ground-detector schemes now in use have shortcomings of one form or another. Some are erratic in operation and cannot be relied upon to detect part or all of the possible grounds. Others are objectionable from the standpoint of the effect that they might have on the generator bearings or insulation. If by some means a shaft ground is provided, the voltage divider bridge method becomes equal to any scheme which is now in use, including the direct-voltage method, and becomes superior in that it does not apply higher-than-normal voltage to the field insulation.

Rewinding A-C Generators for Improved Performance

W. G. SELINE
ASSOCIATE MEMBER AIEE

THE Shawinigan Water and Power Company has an installed capacity of 1,500,000 horsepower in six hydroelectric plants all located on the St. Maurice River in the province of Quebec. The company maintains its own electrical repair department and rewinds all its own generators. During the last 10 years nine machines totalling 240,000 kva have been rewound.

Two years ago the company had the problem of rewinding the first of a group of five generators that had originally been overrated with a temperature rise of 110 degrees centigrade (C). The problem was to reduce the rise to a more normal value without reducing the output. Some fundamental design changes were made to reduce the operating losses and a new insulation structure developed with greater thermal conductivity. Test results indicated that the new insulation had an appreciable effect on temperature reduction. Subsequently the same type of insulation was applied to another generator with different output, voltage rating, and original insulation. Again an appreciable decrease in temperature rise occurred.

This insulation is now standard in this company for all rewind jobs and the results of better heat conductivity are used to reduce temperature rise where required but more generally to increase the kilowatt output when adequate capacity is available from the turbine or the kilovar output where sufficient field and exciter capacities exist. This paper describes the operating history of the machines, their original insulation components, the new insulation and the results of rewinding on the temperature-rise-versus-output characteristic.

18,500-Kva Generators

These units are rated 18,500 kva, 6,600 volts, 0.85 power factor (pf), 120 rpm, 60 cycles, and are hydraulic-turbine-driven. They were installed in 1914 and had been guaranteed to deliver rated output with a 110 C temperature rise with no unduly harmful effects to the insulation. The exact reason for this unusual rating has been obscured by lack of records. They have the following operating history. After 10 years the end-turn cambric insulation was dry and brittle and was replaced by mica tape. There were few breakdowns over the ensuing 15 years. Subsequently, however, the frequency of failures increased to such an extent that all stator coils were reinsulated as a temporary expedient during the war. The majority of faults on these machines were turn-to-turn short circuits caused by vibrating strands. The bonding varnish on the conductor had deteriorated by heat aging and allowed the strands to vibrate and wear away the turn insulation. These characteristics are common to most failures in older machines in this company. The reinsulation process was good for 8 to 10 years, then strand vibration again caused failure.

When the decision was reached to rewind completely these units, a study was made to determine means to reduce the temperature rise but to maintain the output and to provide more heat-resistant insulation components on the conductor to eliminate the vibrating strands.

Table I. Generator Losses in Kilowatts at 18,500 Kva, 6,600 Volts, 0.85 Pf

Loss	Before Rewind	After Rewind
Windage and friction	58	66
Core	221	162
Stray load	112	88
Stator I^2R	131	122
Field I^2R	151	119
Total	673	557
Temperature rise, C	110	52

Paper 55-132, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 21, 1954; made available for printing December 7, 1954.

W. G. SELINE is with The Shawinigan Water and Power Company, Trois-Rivieres, Quebec, Canada.

The author wishes to acknowledge the work done on this project by Prof. W. H. Schippel, McGill University, and numerous associates in his company.

In the absence of manufacturers test data, retardation tests were made to establish and segregate the machine losses. These are shown in Table I. Analysis of these losses and the machine construction showed that the following design changes could be made to reduce losses:

1. With a more efficient insulation structure the stator conductor section could be increased to reduce the stator copper loss.
2. By increasing the stator coil pitch by one slot, the core loss could be reduced. The effect of this change on the short-circuit ratio and wave form were found acceptable.
3. As a result of change 2 the field current and losses would be reduced.
4. By more efficient stranding and transpositions, the stray losses could be reduced.

The results of these changes as established by retardation tests after rewind are also shown in Table I.

It was found however from the temperature-rise-versus-loss characteristics that these loss reductions were not sufficient to reduce the rise to a value near the 60 C standard. Hence a program of experiment and research was conducted to find an insulation structure with better thermal conductivity.

Fig. 1 shows a section of the original stator coil of the 18,500-kva generator. Numerous tests were made with various

combinations of insulating materials and the final structure selected was as shown in Fig. 2. For greater heat stability class-*H* silicone bonded components were used at the core of the coils where hottest-spot temperatures were attained and the previous troubles had started. Experiments indicated that glass-backed mica as compared to formerly used paper-backed mica had better thermal conductivity. The ground and end-turn insulations were made with glass-backed asphalt bonded mica tape, vacuum-pressure impregnated with asphalt compound.

During installation all means were taken to improve the cooling characteristics of the coils. They were hot-pressed into the slots with hydraulic rams to ensure intimate contact of the insulation with the slot walls and to eliminate insulating air films. Special end-turn blocking and spacing of the coils exposed a maximum of coil surface to the cooling air.

The effects of the winding and insulation changes on temperature rise are shown in Fig. 3. Curve *A* is the characteristic before rewinding and curve *B* after rewinding. Analysis of these shows that, had the losses alone been reduced from 673 kw to 557 kw, the temperature rise would have been reduced 24 C. But combined with the improved insulation, a total reduction of 58 C was realized. The temperature-rise-versus-output curves of Fig. 4 show the increase in output with the machine considered on the basis of 60 C rise.

40,000-Kva Generator

Following the successful application of this insulation on the foregoing machine, an opportunity arrived to use the same components on a larger, higher voltage generator whose original insulation was different. This unit was rated 40,000 kva, 11,000 volts, 0.75 pf, 138.5 rpm, 60 cycles, and was installed in 1928. The original stator insulation is shown in Fig. 5. This unit had no failures until 1952. At that time inspection showed local overheating of the top end turns to the extent that the strand insulation had completely disintegrated on many coils. This heating was diagnosed as having been caused by lack of spacing between end turns, resulting in poor ventilation in this area. In this case there was no problem of general excessive temperature rise. It was planned to reduce the local heating of the top end turns by spacing the coils in this region. The rewinding procedure and insulation components were the same as used on the 18,500-kva generator but adequate for the higher voltage.

The results of this rewind on the temperature rise characteristic are shown in Fig. 6. Since the original temperature rise of this machine was normal, the benefits of the new insulation were taken in increased output. This amounted to 9,000 kva or 24 per cent over the original rating of 40,000 kva. This was mostly reactive power, as the output of the turbine was limited.

Conclusions

Excluding the obvious effects of loss reduction in the case of the 18,500-kva generator, the lower temperature rises of these machines are attributed to the better thermal conductivity of the glass-backed and silicone-impregnated insulation components, and the added radiating surface of the spaced end turns. It is hoped that the application of class-*H* components at the hottest parts of the winding will deter the past troubles caused by vibrating strands.

◆

Discussion

E. C. Whitney and **Graham Lee Moses** (Westinghouse Electric Corporation, East Pittsburgh, Pa.): This paper discusses interesting improvements resulting from design changes made on the winding and perhaps other parts of the machine. It reports that the pitch of the winding was increased and the core loss, short-circuit ratio, and field loss were all reduced. From inspection of the illustrations, it would appear that the eddy factor in the original coil was poor and numerous short circuits between bare strands would be expected if the construction was as pictured. Although not stated in the paper, it may be that an improved transposition was used on the new coil in addition to the increase in conductor cross section described.

Elimination of the slot cell will usually decrease the winding temperature from 5 to 10 degrees by detector because of better cooling of both the coil and the detector. Improved ventilation from other causes could also have contributed to the lower winding temperature, although these are not described. For example, wedge construction can be modified to permit better ventilation. Furthermore, a new clean winding can be expected to be cooler than an old dirty winding. The information on windage and friction loss might be interpreted to indicate that there was a change in the blower design, although this was not brought out in the paper.

The paper does not describe how the temperature was measured and no detector is shown in the illustration. It would be interesting to know whether the coil temperature was measured in the slot part or in the end winding. Thermal conductivity of the insulation wall is an important factor, but our experience does not indicate that the temperature by the standard AIEE detector would be affected as much as has been reported in this paper. On the other hand, the hot-spot temperature is much more affected by the thermal conductivity of the insulation than is the temperature as observed by standard detectors.

H. R. Sills (Canadian General Electric Company Ltd., Peterborough, Ont., Canada): Mr. Seline has, by the direct approach of rewinding his own machines, rather forcibly presented the user's point of view in respect to machine design and the characteristics desired. In this respect the approach is unique and the data given will be of considerable value to designers in formulating their design concepts.

However, in 1914 the majority of generators were designed primarily about their self-regulating characteristics and many machines of that period have since been rewound, using modern insulations and winding practices, for twice their original rating, but at sacrifice of their self-regulating characteristics.

The material which Mr. Seline has at his disposal for rewinding these generators was not available when the machines were built. This, of course, is the problem in evaluating insulation practices. Those that fail are already obsolete.

It is of interest to observe that in both instances the failures originated in the strands and turn insulation. The failure on the 40,000-kva generator windings was caused by carbonization of the cotton strand insulation lying in a section of the core overheated because of oil contamination. In the line terminal coils, this carbonized strand insulation was completely destroyed by internal ionization which was progressively attacking the turn and slot insulation. These coils were overheating because of circulating current losses as a result of the loss of the strand insulation.

However, the condition of the turn and slot insulation in the neutral coils where there was not ionization was such as to make it appear that, had the strands been class-*B* insulated, as is now done, they would have withstood the temperatures and there would have been no interstices for internal ionization to do its deadly work.

In Fig. 6, the curves replotted against the square of the load, and extrapolated as straight lines to no load, indicate that there has been a reduction of no load temperatures of 6 C. Is this caused by a change in pitch of the coils? If so, this leaves an improvement of 4 degrees at rated load due to improved conductivity of the insulation. It would be of interest to know how much of this should be attributed to the improved thermal conductivity obtained by pressing the coils into the slots.

The author has made a valuable contribution and I am sure it will be of much interest to machine designers. The increased loadings will produce higher thermal gradients in the insulation and it will be interesting to know how well this composite class-*H* and class-*B* insulation will sustain the test of operation.

A. W. W. Cameron and K. R. Knights (The Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada): The Shawinigan Water and Power Company is to be congratulated in taking this trial step forward in a field where too few such steps have been taken over the past 30 or 40 years. It would appear, in view of the relatively high cost and reported susceptibility of silicone insulations to deterioration in air at the higher voltages, that the company was wise in limiting the silicone application to the inner insulation of the coils where temperature and rate of deterioration are possibly the highest.

We would like to enquire whether some credit for reduced temperatures could be given to the cleaning action that resulted from replacing the windings, and whether the reduced temperatures will cause any difficulty in heating of the generator room during winter months.

It is of interest to note that glass-backed mica tape was used for the ground insulation. The author's opinion would be appreciated on whether the lower mica content obtainable with glass-backed as compared to paper-backed mica tape would limit its applicability to new generators.

We are very interested in this application of silicone-insulated compound to waterwheel generator insulation, and are hoping that the company will carry out and make available the results of a testing program to provide information on the relative rate of deterioration of these windings.

W. Hindle (Canadian Westinghouse Company Ltd., Hamilton, Ont., Canada): We would like to compliment Mr. Seline for providing some very important information on the subject of rewinding a-c generators. He has shown how it is possible to incorporate most of the improvements which have evolved since 1913 in generator design into the rewinding of some of the oldest generators in Canada.

It would be interesting to review briefly the history of the Grand Mere generating station involved in the first part of the paper. The six original machines reported by Mr. Seline, according to our records were rated 14,700-kva, 80 C rise, with a short-circuit ratio of 1.30, and the 18,500-kva 110 C rating was likely an overload rating.

In 1923, we supplied two generators of the same physical dimensions, rated 18,500-kva 75 C rise by thermometer, which tested 65 C by detector. This rating was obtained by a change in the number of slots and by increasing the amount of iron by approximately 3 per cent while still maintaining a short-circuit ratio of over 1.00. In 1940, we rebuilt one stator, supplied new field coils, modified the ventilation, and rated the rebuild 20,000-kva 60 C rise, with a short-circuit ratio of 1.00. We have no record of temperature test on this rebuild, but are of the opinion, based on design calculations and tests on similar machines, that the rise would be approximately 45 C.

The stray load loss in the author's design has been reduced, in line with modern current practices, by designing coils with thinner strands including transpositions. Mr. Seline, in a very clever way, has arranged the individual strands of the coil so that each strand is completely insulated from each other.

We note that in this rewind the coil pitch has been increased with a consequent reduction in the field current but at the expense of the short-circuit ratio. On previous designs, the limiting factor on rewinding for increased rating has been the short-circuit ratio of 1.00, and we feel that some considerable part of the improvement in rating is because of the reduction of the short-circuit ratio.

A present-day generator built on the same size frame would be rated 27,000 kva, 60 C, with a short-circuit ratio of 1.00. This generator would incorporate thermalastic insulation and the latest improvements in ventilation.

In conclusion, we feel that Mr. Seline is placing undue stress on the thermal properties of silicon varnish and that other factors have contributed such as changes in ventilation of the generators. It would be interesting to compare the rewind performance of a succeeding generator using another type of modern insulation.

J. A. Langford (Canadian-Brazilian Services, Toronto, Ont., Canada): The subject of this paper is of considerable importance to all those responsible for the operation of generators. The author has presented a very interesting account of the work of his company and he and his company are to be commended for their pioneering with silicone insulation.

Table I contains information on the losses of the 18,500-kva generators before and after rewinding. It is noted that, after rewinding, the windage and friction losses increased by about 14 per cent. Does this indicate that the quantity of air circulating through the generators was greater after rewinding?

In discussing the composition of the tape used for ground insulation, the statement is made that experiments indicated that glass-backed mica as compared to formerly used paper-backed mica had better thermal conductivity. The results obtained with the new insulation bear out the conclusions derived from experiments. From the standpoint of thermal conductivity, the only difference between glass-backed and paper-backed tape would appear to be that, for a given thickness of insulation, there would be a greater proportion of backing material in the glass-backed tape. However, this difference would not seem to account for the improved performance of glass-backed tape. Could the fact that glass-backed tape can be wound on with more tension and can, therefore, produce tighter insulation be part of the answer?

W. G. Seline: I appreciate the interest shown by the various discussers in this paper. Mr. Whitney and Mr. Moses are correct in their observation that the original coil stranding was very inefficient. The large strand sizes caused excessive eddy currents within the strands, the

Table II

Output, Kilovolt-Amperes	Guaranteed Approximate Temperature Rise, C
14,700	75
16,000	85
18,500	115

construction of the turn section did not give adequate protection against strand-to-strand short circuits, and no transpositions were made to reduce eddy currents between strands. As stated in the paper, transpositions were used on the new coils.

With regard to temperature reduction to be expected from elimination of slot cells, modified wedge design, and new clean windings, our past experience has been very discouraging. We have rewound four 35,000-kva and two 15,000-kva 6,900-volt generators where the original insulation was mica folium with a slot cell. The rewinds were made with continuous paper-backed mica-taped asphalt-impregnated coils with no slot cell. Wedges were modified by fluting for more efficient air passage. The machines were thoroughly cleaned during rewind. In the case of the 15,000-kva generators, the stator copper section was increased 5 per cent and the transpositions were employed. In all these cases the temperature rise before and after rewind remained substantially the same.

It is on the basis of this experience with mica folium and paper-backed mica tape versus the new glass-backed mica insulation structure that we conclude that the major portion of the temperature reduction comes from the better heat conductivity of the new insulation components. The increased windage and friction loss may have been the result of increased bearing friction as these underwent extensive overhauling. No alterations were made to the blowers.

Temperature measurements were made by resistance temperature detectors between coil sides at the center of the slots. The decreased temperature at this point may have resulted from the dissipation of a greater proportion of the heat from stator copper losses through the winding end turns. From experiments which approximated operating conditions, we found that the difference between the hot-spot copper and detector temperatures was of the order of 1 to 2 degrees for the new coils and 6 to 8 degrees for paper-backed mica taped coils. These experiments were made on 6,900-volt insulation.

In reply to Mr. Sills, no changes were made to the pitch of the stator coils on the 40,000-kva generator.

Regarding the discussion of Mr. Cameron and Mr. Knights, it is to be expected that the heating of the generator room will be reduced as a result of the reduction of operating losses. However, with only two of five machines presently rewound, this has not yet been noticeable.

The glass-backed asphalt bonded mica tape is approximately 0.002 inch thicker than the formerly used paper-backed tape. However, the space factor is approximately the same considering the tighter application possible and the omission of binders previously used. Compared with mica folium it eliminates the use of slot cells and bulky spacer strips between coil sides. We can see no reason why this insulation cannot be used on new machines. It is anticipated that a co-ordinated testing program will be instituted to evaluate the comparative rate of deterioration of these windings.

Referring to Mr. Hindle's review of the history of the 18,500-kva generators, our knowledge of this and the basis upon which the machines have been operated over the past 40 years is as follows:

1. The original contract stated that the coils could withstand a temperature of 150 C continuously without deterioration.
2. The original contract specified temperature rise not to exceed 55 C (above 25 C ambient) at 14,700 kva.
3. Under test the machines failed to meet the temperature rise clause and a supplemental agreement was drawn up to provide new temperature specifications, as given in Table II. The supplemental agreement also reiterated that the coils were insulated to withstand a maximum total internal temperature of 150 C. It also stated that if the generators were operated at a rise of 115 C or lower (above 30 C ambient), there would be no harmful effect on the insulation.

On the basis of this contract, the generators were rated 18,500 kva continuous operation and name plates were supplied by the manufacturer accordingly.

The two machines supplied in 1923 and the one rebuilt in 1940 were of a considerably modified design. It is agreed that a machine of greater output can be built within the same physical dimensions with an improved design and lower loss steel. This was actually the alternative available at the time of rewind. However, by only a slight modification of the electrical design and the use of these new insulation components, an equivalent result was accomplished at one-fourth the cost.

As noted in Table I, a considerable proportion of the loss reduction was in the core by increased stator coil pitch. This reduced the short-circuit ratio from 1.05 to 0.80. This was found acceptable under present system conditions.

In reply to Mr. Langford, the glass-backed tapes can be applied with considerably more tension and, undoubtedly, the resulting compactness would aid heat conductivity.

A Transductor-Type Field Ripple Detector for Synchronous Generators

H. M. McCONNELL
ASSOCIATE MEMBER AIEE

IT HAS been recognized that negative sequence stator currents in synchronous generators, if allowed to persist, may cause dangerous heating of the rotor structure due to induced currents. The problem of protecting synchronous generator against rotor heating from this cause has stimulated an active discussion among those responsible for relay application.

The present method of detecting negative sequence stator current is to employ well-known sequence-filtering networks fed by current transformers. The output of the network is used to operate a relay which actuates protective equipment if the permissible I^2T, or integrated square of negative sequence current, is exceeded. A group of recent papers[1-5] summarize the present state of development in this matter.

At the time of the presentation of these papers, it was mentioned in oral discussion that a method of detection of negative sequence currents based on the induced a-c component of field current would be desirable.[6] It is well known that a proportionality exists between these quantities. However, a conventional current transformer is not satisfactory in detecting the a-c component of field current, because of the presence of the steady d-c component which saturates the transformer.

This paper presents a circuit for the measurement of the a-c component of a current which has a considerable d-c level, with particular application to the field ripple problem at hand. The circuit consists of current transformer with an additional compensating winding supplied by a current transducer whose function

H. M. McCONNELL is with the Carnegie Institute of Technology, Pittsburgh, Pa.

The work reported in this paper was supported by the Office of Naval Research, under Contracts *N7ONR 30308*, Projects *975-272* and *275*. The author is grateful for the assistance of Hugh McK. Lynch, and to Magnetics Incorporated of Butler, Pa., for some of the experimental apparatus.

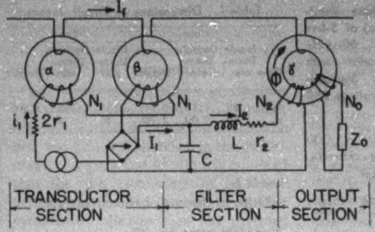

Fig. 1 (left). Circuit diagram of the transductor-type field ripple detector

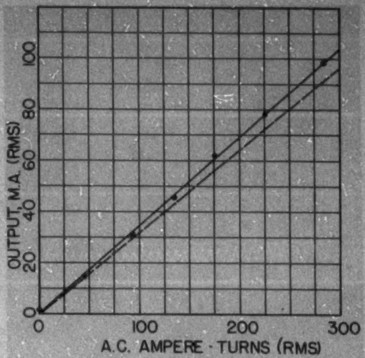

Fig. 2 (right). Steady-state output characteristic at 60 cycles, with 400 ampere-turns d-c, and 585-ohms resistive load. Dashed curve calculated by equation 7; solid curve measured

is to cancel the d-c ampere turns. The circuit is shown in Fig. 1. The cores are made in gapless (toroidal) form, of a material having essentially a rectangular hysteresis loop.

Design Objectives

The objectives in designing the circuit are to achieve: 1. a useful output current I_0 into the burden Z_0; 2. faithful response to sudden changes in either the d-c or a-c components of the current I_f; 3. acceptable linearity between I_0 and the a-c component of I_f. An approximate analysis of the circuit indicates the way in which the various circuit components must be chosen in order to meet these objectives.

Analysis

The transductor will be idealized by stating that the instantaneous current I_1, Fig. 1, is the image of the instantaneous current I_f. Reasonably close agreement between this idealization and actual performance is obtained if the resistance drop in the a-c windings of the transductor, $2r_1i_1$, is small compared with the maximum applied voltage, and the capacitor C offers low impedance to the a-c component of I_1. A detailed analysis of the transductor operation is beyond the scope of this paper; in fact, the performance of the series-connected magnetic amplifier with high-impedance control circuit is not well understood because of unexplained core behavior. An analysis of circuits of this type, making use of an idealized flux-density/field-intensity characteristic for the core material, is available in the literature.[7] It is sufficient to note here that the compensating turns of the current transformer may be adjusted to account for linear departures of the transductor performance from the ideal. Thus

$$I_1=\frac{I_f}{N_1}k_1 \tag{1}$$

where k_1 is the proportionality factor which accounts for the current ratio error of the transductor.

For perfect compensation of the current transformer

$$N_2I_{1(\text{d-c})}=I_{f(\text{d-c})} \tag{2}$$

therefore

$$N_2=\frac{N_1}{k_1} \tag{3}$$

The current transformer is idealized by neglecting its magnetizing current. Then, the ampere-turn relationship states that

$$I_{f(\text{a-c})}=N_0I_0+N_2I_{2(\text{a-c})} \tag{4}$$

The common flux ϕ of windings N_0 and N_2 require that

$$I_0Z_0=j\omega N_0\bar{\phi} \tag{5}$$

$$I_{2(\text{a-c})}(r_2+j\omega L)=j\omega N_2\bar{\phi} \tag{6}$$

The reactance offered by C at the ripple frequency $\omega/2\pi$ is not included in equation 6 because the conducting arms of the rectifier bridge effectively short-circuit C to this component of current.

Combining equations 4, 5, and 6 yields the complex ratio of transformation

$$\frac{I_0}{I_{f(\text{a-c})}}=\frac{1}{N_0\left\{1+\left(\frac{N_2}{N_0}\right)^2\left(\frac{Z_0}{r_2+j\omega L}\right)\right\}} \tag{7}$$

The rapidity with which the bias current $I_{2(\text{d-c})}$ is able to adjust to transients in the d-c level of I_f will have an effect upon the current transformer behavior. During transient intervals both the d-c and a-c components of field current change suddenly. The current transformer can by itself reproduce such asymmetrical currents in its output winding for a short time only; this time is dictated by the rate at which the average flux level of the current transformer core increases, which is in turn dictated by the burden.

It will be assumed here that the current transformer is unable to reproduce asymmetrical currents unless perfect compensation in the bias winding exists. Then a suitable transient response of the bias current I_2 will be defined as follows: the bias current should reach a level such that compensation is restored within an interval which is short in comparison with the short-circuit transient time constant (T_d') of the generator. Taking 20 cycles as a representative value of T_d', then the bias current should be able to reach the level for compensation in about 4 cycles at fundamental frequency.

Transients in the bias circuit will be calculated under assumptions that: 1. the transductor delivers a direct current I_1 proportional to the d-c component of I_f; 2. the current transformer is saturated. Then, the bias winding (N_2) may be treated as a resistance, and the circuit L, r_2, C may be considered to receive a prescribed current. Rapid response with a minimum tendency to overshoot in a circuit of this type is achieved if the damping is somewhat less than the critical value. Accordingly, a damping ratio of 0.7 will be assumed. Previous discussion of response time has indicated that about 1/15 second may be allowed between initiation of a sudden change in I_1 and a corresponding response of I_2. As shown in any treatment of second-order systems of this type, the following relationships are established

$$\left\{\begin{aligned}&\frac{r_2C}{2\sqrt{LC}}\cong 0.7\\&\frac{1}{\sqrt{LC}}\frac{1}{15}\cong 2.5\end{aligned}\right. \tag{8}$$

or

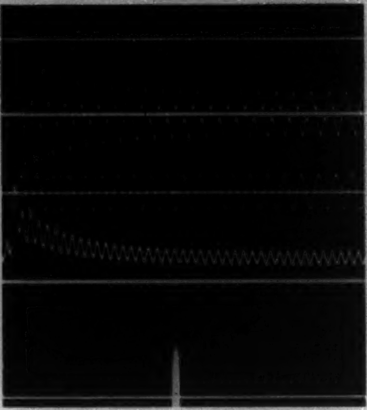

Fig. 3. Single-phase short-circuit (line to line) of 5-kva 230-volt 3-phase 60-cycle salient-pole generator with damper winding. Star-connected. No-load voltage 250 volts

Top—Output current to 1,000 ohms. Final value 86 ma, peak to peak

Second—Transductor supply current

Third—Transductor supply voltage, 60 cycles

Fourth—Current transformer bias current. Initial value 33 ma

Bottom—Generator field current. Initial value 2.29 amperes

$$\begin{cases} \sqrt{LC} \cong 0.0267 \text{ second} \\ r_2C \cong 0.0373 \text{ second} \end{cases} \tag{9}$$

Whether the conditions of equations 9 may be realized depends on whether the filter circuit Q prescribed by these equations is practical. It is found that at the ripple frequency of 120 cycles the ratio $(\omega L/r_2)$ dictated by equations 9 is about 14, which is readily obtained with commercial components.

Let it be required to design a field ripple detector for a generator in which during transients, the d-c component of field current may reach 400 amperes. The initial value of a-c component of field current under such circumstances will be less than a 400-ampere peak, by an amount equal to the initial field current. However, let it be assumed for purposes of design that the peak a-c component will be 400 amperes; the detector should be designed for an a-c level of 283 amperes rms. Let a burden of 10 volt-amperes at 1,000 ohms be required at this a-c level. These preliminary considerations fix the current transformer output at 100 milliamperes (ma) rms, and the current transformer output winding can have no more than 2,830 turns. The current transformer core must be capable of at least 100/2,830 volts per turn at 120 cycles.

Equation 7, together with the value of $Q=14$ dictated by equations 9, allows the determination of N_0 and N_2 versus the parameter (N_2/N_0) for a given value of the second parameter r_2. If r_2 is assumed to take a certain value, then N_0 and N_2 may be found such that the wire sizes, available winding spaces, and practically available choke fit the assumed value of r_2. Several trials of this nature indicate the combination best suited to the particular application considered. It is found that in the present example N_2 should be about 5,000 and N_0 should be about 2,200 if it is assumed that r_2 is 500 ohms. The corresponding value of L is 9.30 henrys. The rated value of the compensating current I_2 becomes 80 milliamperes and the rectifier must withstand 40 volts d-c. The capacitor should be about 75 microfarads, although the exact value is not critical; see equation 8.

Experimental Work

A model of the circuit has been constructed and tested. The three cores were made of 0.004-inch Orthonol tape. The dimensions in inches are shown in Table I.

Table I. Dimensions of Circuit, Inches

	Core			Box		
Core	Inside Diameter	Outside Diameter	Height	Inside Diameter	Outside Diameter	Height
α, β	1.25	1.75	0.50	1.18	1.82	0.61
γ	1.50	2.00	1.00	1.40	2.10	1.11

Other constants of the circuit are:

$N_1=5{,}000$ turns No. 32
$N_2=5{,}000$ turns No. 32
$N_0=2{,}200$ turns No. 32
$2r_1=304$ ohms, 20 degrees centigrade
$r_2=501$ ohms, 20 degrees centigrade
$L=10.5$ henrys, nominal
$C=50$ microfarads, 50 volts electrolytic

A factor k_1 was introduced in equation 1 to account for the fact that the ampere-turn ratio of the transductor is slightly less than the ideal of unity. It will be noted that both N_1 and N_2 are 5,000 turns in the model. The factor k_1 is introduced in an equivalent way in the model by placing more exciting turns upon the transductor cores than upon the current transformer core, turns being added until maximum output current is reached at rated d-c and a-c excitation levels. It was found that 72 turns on the transductor cores and 69 turns on the current transformer core achieved this result. Thus $k_1=69/72=0.958$. Rated d-c current becomes 5.80 amperes and rated a-c ripple current becomes 4.08 amperes rms. (The example design began by assuming 400 amperes in a single conductor to be the excitation level. To test the model on available machines, the nominal 70-turn exciting windings were installed. In a single conductor application it would be

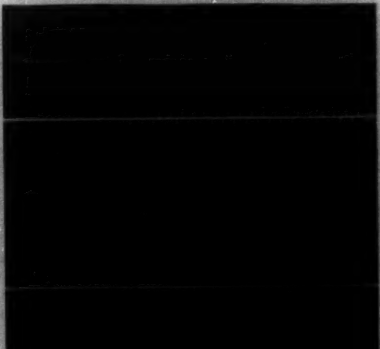

Fig. 4. Single-phase short-circuit (line to line) of 100-kva 2,300-volt 3-phase 60-cycle salient-pole generator without damper windings. Star-connected. No-load voltage 1,500 volts

Top—Output current to 1,000 ohms. Final value 230 ma peak to peak

Second—Transductor supply current

Third—Transductor supply voltage, 60 cycles

Fourth—Current transformer bias current. Initial value 50 ma

Bottom—Generator field current. Initial value 4.0 amperes most convenient to add extra turns to the current transformer compensating winding, in about 1/2 per cent taps, in order to "tune" for best compensation.)

The steady-state response of the unit at 60 cycles is given in Fig. 2. Transient response, in the situation for which the unit was designed, is shown in the oscillograms of Figs. 3 and 4. (It will be noted that the d-c component of generator field current in Fig. 4 rises to a value considerably greater than the designed level, resulting in some distortion of the output current wave form and a reduction in its rms value.)

Conclusions

The device presented in this paper is shown to be a small, inexpensive, static apparatus for the measurement of the a-c component of field current in a synchronous generator, both in the transient and steady states. It has sufficient output to operate a relay or meter. Its design is simple, and its components are readily obtained.

Probably the most serious obstacle to the application of this device to generator protection is the determination, without dangerous tests, of the amount of a-c ripple in field current per unit of generator negative-sequence current.

Accurate calculations are possible in the case of salient-pole generators. However, the presence of solid iron in the rotor forging of a turbogenerator upsets any formal calculation for those machines.

Discussion

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.): In the discussion of an earlier paper (see reference 6 of the paper) it was reported that current transformers with air gaps, or similar equipment, have been in practical operation for relaying by using a-c currents in the rotor circuits. The transformer proposed by Dr. McConnell makes possible further improvements of such protective schemes and deserves the serious consideration of those who design, build, or use protective relays.

In this paper, particular emphasis is placed on double-frequency currents in the rotor and rotor windings. It would be of interest to learn whether the author has also considered the behavior of his device with regard to low-frequency rotor currents which are typical of other important disturbances.

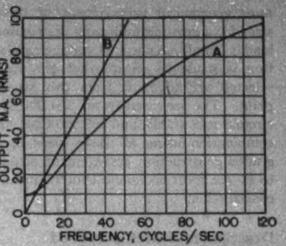

Fig. 5. Calculated performance of ripple detector circuit with 400 ampere-turns d-c and 283 rms ampere-turns a-c at various frequencies, operating into a 1,230-ohm total resistance burden. Curve A—output current. Curve B—output current capability without saturation of current transformer

H. M. McConnell: The response of the circuit to currents of frequency different from 120 cycles can be calculated from equation 7, if the output current transformer does not saturate. For constant d-c and a-c ampere-turns, but variable frequency, the output decreases with decreasing frequency because of the shunting effect of the filter section. This behavior is shown in Fig. 5, in which is also shown a line representing the capability of the current transformer core, in terms of current which can be supplied to this particular burden without saturation.

A Method for Determining Economical ACSR Conductor Sizes for Distribution Systems

A. W. FUNKHOUSER
ASSOCIATE MEMBER AIEE

R. P. HUBER
NONMEMBER AIEE

IN CONVERTING the 4-kv fringe area of the Indianapolis Power & Light Company system to 13-kv distribution, it was decided that, wherever possible, all new line construction would be made using bare steel-reinforced aluminum cable (ACSR) type of conductor. The economy of this type of conductor over copper has been well established in connection with transmission lines by the experience of many companies including the Indianapolis Power & Light Company. Since the application of ACSR was new to this company's distribution system, it was necessary to set up certain sizes as standard. The problem was in selecting as few sizes as possible to minimize stocking while still providing the most economical conductor for the loadings anticipated. It was also necessary to consider voltage regulation at the maximum allowable load conditions. A method is presented for making these selections in which a mathematical solution for determining the economic proportions of different wire sizes in a graded construction arrangement is used. It is believed that this offers a different approach to this problem from that used in other economic wire size studies.

In selecting the wire sizes for use on this system, an economic comparison of the various sizes is made in two ways. First, the most economical sizes for any value of load is determined. Second, the

Paper 55-159, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 13, 1954; made available for printing December 15, 1954.

A. W. Funkhouser and R. P. Huber are with the Indianapolis Power & Light Company, Indianapolis, Ind.

most economical arrangement of these sizes for a growing uniformly distributed load is found. A check of voltage regulation is made to ensure that the sizes selected are adequate from this standpoint. The sizes used are no. 2/0, 266,800 circular mils (CM), and 397,500 CM. A combination using all three sizes in a graded construction arrangement proves to be the most economical for main line construction.

Description of Methods Used

The major considerations in selecting certain conductor sizes as standards are the comparisons of annual cost and voltage regulation of all sizes, and under all conditions likely to develop. Variations in load distribution, load factor, load-growth rate, loss charges, investment charges, and construction costs all affect the economical conductor sizes to be used. These factors vary from system to system and must be based on company accounting practices, operating conditions, and anticipated future conditions. Differences in voltage regulation were not evaluated in the economic comparison of conductor sizes, but data are included showing the relation of conductor size (and therefore, cost) to voltage regulation. The reduction in voltage drop is a factor favoring the larger conductor sizes when the economic comparisons are close.

In this study the economical conductor size is first established for each value of load up to a maximum allowable loading of 6,000 kva for the 13-kv circuits. One of these sizes can thus be selected for any line serving a static concentrated load within the range studied. However, most circuits have a growing load that is distributed along its entire length. To determine the most economical arrangement under these conditions, the established conductor sizes are compared individually and in various combinations to ascertain the lowest annual cost for the conditions assumed. As a further check, the regulation for the most economical combination is calculated to see if it is adequate from the voltage standpoint.

Conditions Assumed

In making up the cost comparison studies for this system, it is found that certain simplifying assumptions can be made. The cost of poles and hardware can be left out altogether. Span lengths are limited by existing pole-line spacing, service drop requirements, and joint-use telephone line specifications rather than by conductor size. The pole size is also limited by telephone contacts, and the lowest class pole used on the main distribution lines will support the largest conductor size being considered. Hardware costs are neglected since a check of the difference in cost on the system showed it to be negligible compared to the total cost per mile involved. All hardware is the same for the conductor sizes studied except for a few dead-end clamps.

The geography of the fringe service area and the location of the initial 132/13-kv substations determined the average circuit length at approximately 10 miles. The maximum circuit loading under normal conditions is limited to 6,000 kva. In determining the maximum allowable circuit loading, a value as large as practical was selected to take advantage of reduced switchgear requirements. It was also necessary to keep the number of lines to a minimum since a congestion of subtransmission lines already existed around the substation sites to be used. The limiting factors are as follows:

1. A reasonably good voltage regulation must be maintained on the 10-mile line.
2. The ratio of normal load current to available short-circuit current must allow for relay settings to give reasonable fault sensitivity.
3. The number of customers affected by a circuit outage must be taken into consideration.

It is believed that the higher voltage permits better co-ordination between oil circuit breaker, recloser, and fuse, and, with the emergency ties between circuits, the customer outage rate at this maximum circuit loading is comparable to the present 4-kv radial service.

Wire sizes are limited to a minimum of no. 2/0 since this is the smallest conductor to have still adequate thermal capacity for the maximum load. A maximum size of 397,500 CM is used since the aforementioned hardware and pole cost assumptions do not hold true for larger sizes, and it is expected that increased pole-line costs would tend to offset any loss savings. Use of an all-aluminum conductor was considered, but advantages of less sag, use of existing standard stock conductors, additional strength to allow for damaged strands, and ability to withstand high temperatures due to emergency overloads were believed to offset the slight additional cost of ACSR using a single steel strand.

For ACSR wire sizes larger than no. 4/0, the 18/1 type of stranded arrangement is used for all except the 300,000-CM size. This stranding was chosen since previous studies had shown it to be the most economical for the span lengths encountered. A 26/7 stranding is used for the 300,000-CM size since it was the only design on which data were available from the catalogue. All these larger sizes are of 2-layer construction which reduces the losses in the steel core. For no. 4/0 and smaller sizes, the 6/1 stranding using a 1-layer construction is employed. The effect of greater losses in the 1-layer construction can be seen later when nos. 3/0 and 4/0 wires never prove to be economical for any value of static loading.

Labor costs are the most difficult to establish because the time actually spent in installing wire is not usually segregated in the cost records. It is thought that labor costs would be largely determined by the weight of the conductor. In this study, labor costs for the ACSR conductor were based on estimated costs per pound for installing a copper conductor on the existing system. The values used for each size of wire are given in Table I.

Economic Comparison for Static Loads

The first step in the economic study is the determination of the annual costs of investment and losses per circuit mile for each size of conductor and for a range of loads up to the maximum allowable load per circuit. The cost values used are also given in Table I. The results of this

Table I. Costs and Load and Conductor Characteristics

Demand Charge = $150 per Kilowatt
Energy Charge = 0.004 per Kilowatt-Hour
Load Factor = 40 Per Cent
Loss Factor = 25 Per Cent
Fixed Charges = 15.5 Per Cent of Investment
Annual Cost of Losses = $32 per Kilowatt

Size	Stranding	Ohms per Mile	Cost per Pound, $		Installed Cost* per Mile of 3-Phase Circuit, $
			Material	Labor	
No. 2/0	6/1	0.895	0.2765	0.147	1,229
No. 3/0	6/1	0.723	0.2750	0.1395	1,515
No. 4/0	6/1	0.592	0.2750	0.1299	1,869
266,800 CM	18/1	0.385	0.330	0.1302	2,114
300,000 CM	26/7	0.342	0.316	0.1106	2,788
336,400 CM	18/1	0.306	0.322	0.1182	2,544
397,500 CM	18/1	0.259	0.3145	0.1078	2,882

* Cost of neutral wire not included because same size is assumed for all-phase conductor sizes.

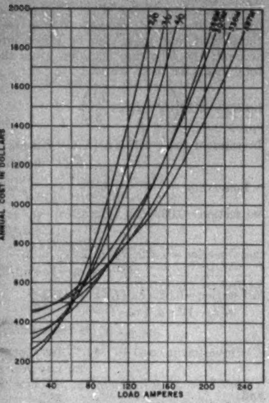

Fig. 1. ACSR distribution conductor annual cost comparison. Line length = 1 mile, static load concentrated at end of line, line cost includes conductor costs and installation labor only, loss cost = $32 per kilowatt, and fixed charges = 15.5 per cent

study are illustrated by the curves in Fig. 1. From these curves the following wire sizes are shown to be the most economical for the range of loads listed:

0 to 54 amperes, no. 2/0
54 to 96 amperes, 266,800 CM
96 to 114 amperes, 336,400 CM
114 to 260 amperes, 397,500 CM

Since the 336,400-CM and 397,500-CM curves are so close together for the range of loads for which 336,400 CM is the most economical, the extension of the use of 397,500 CM to cover this range is warranted. Thus, the entire range of loads can be economically served by three sizes of ACSR conductor, namely, no. 2/0, 266,800 CM, and 397,500 CM.

Economic Comparison for Growing Loads

The second step in the economic study is to make an accumulated annual cost comparison between established sizes and combinations of these sizes of conductor for a growing uniformly distributed load on a 10-mile line. An initial loading of 2,000 kva and a load growth of 11.6 per cent per year is taken. This allows the load to grow to 6,000 kva over a 10-year period. This initial loading and assumed load-growth rate correspond to the estimated values to be expected on the 13-kv lines when they go into service.

The cost comparisons are shown by the curves in Fig. 2. These curves show the 10-year accumulated annual cost for the various combinations with the ratio of length of large conductor to total circuit length varying from 0 to 100 per cent. The equations used in determining cost are shown in Appendix I. It is interesting to note that, in the development of equations for the determination of the most economical proportioning of sizes in a combination, the total length of line is not a factor. Only the proportion of lengths used in the graded construction arrangement is important.

For the use of one conductor size throughout, the accumulated annual cost for 266,800 and 397,600 CM are approximately equal for a 100-per-cent large conductor, as can be seen on the right-hand ordinate of Fig. 2. The accumulated annual cost of a line with a 100-per-cent no. 2/0 conductor would be substantially higher, as can be seen on the left-hand ordinate of Fig. 2. Calculations were also made for 336,400 CM, which showed it to be the most economical for use of only one size but approximately equal in cost to either 266,800 or 397,500 CM.

If the three chosen sizes are properly proportioned, combinations can be obtained which are more economical than any one size used alone, as shown in Fig. 2, and the use of all three sizes in combination is more economical than the use of only two sizes. In Appendix I, it is shown that the most economical design is obtained when 397,500 CM is used for 44.4 per cent of the total length, 266,800 CM for 26 per cent, and no. 2/0 for 29.6 per cent.

Effect of Load-Growth Rate

The effect of the load-growth rate upon the foregoing comparisons for uniformly distributed load was also investigated. Growth rates between 6 and 16 per cent were assumed and accumulated costs were calculated for both a 10-year period and the period of time necessary for a 2,000-kva initial load to grow to 6,000 kva for each rate. The ratios of wire lengths for the graded construction were taken as that found to be the most economical for the 11.6-per-cent rate. In practically all cases, the use of the three sizes of conductor in graded construction proved to be the most economical.

Effect of Change in Cost of Losses

A review of the calculations was made to determine the effect a change in cost of losses would have on the results. This could be caused by a change in demand and energy charges or by the use of a different method for loss evaluation. It was found that the relative positions of the curves in Fig. 1 remained unchanged but the points of crossover shifted to other load values. The shift of the crossover point will be inversely proportional to the square root of the change in loss cost, e.g., a 44-per-cent increase in loss costs gives $1/\sqrt{1.44}$ or 0.834, which is a 16.6-per-cent decrease in the load value. It was also found that the length of line for the smaller and medium sized conductors in a graded construction follows the same rule. The length of the larger conductor section then becomes $1-1/\sqrt{\text{change}}$.

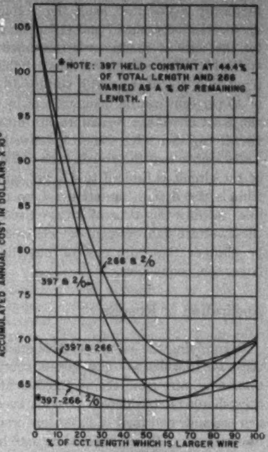

Fig. 2. Economical proportions of ACSR conductors in distribution circuits. Uniformly distributed load along line, length of circuit = 10 miles, initial load = 2,000 kva, final load = 6,000 kva, rate of growth = 11.6 per cent, and period of time = 10 years

Voltage Regulation Considerations

The reductions in voltage drop obtained with the greater investments required for conductor sizes larger than no. 2/0 ACSR are shown in Fig. 3. This curve shows that substantial reduction is obtained for investment in increased conductor sizes up until 266,800 CM is reached at which time the curve tends to bend over rapidly. The wire sizes being studied are seen to fall within the range where the most gain in voltage-drop reduction per dollar invested is found.

A check on the voltage regulation for a 10-mile line showed that, for a 6,000-kva uniformly distributed load, the voltage drop varied between 8.7 and 11.7 per cent for the various conductor arrangements studied. With substation bus voltage regulation, a primary circuit voltage drop of 10 per cent can be taken care of by a single set of voltage regulators out in the circuit together with some capacitor installations so that the drop in each section of the circuit is limited to 4.5 per cent. This is the design limitation set up for lines feeding this type of area. Use of these voltage-improvement devices would be cheaper than the cost of installing larger size conductors.

Application of Results

In applying the results of this study, the ways in which practical circuit conditions may vary from the assumed conditions should be considered. For instance, if a concentrated load of 6,000 kva were to be served at 13 kv, it would have to be much closer than 10 miles to a substation, and a single conductor size of at least 397,500 CM would have to be used.

It is believed that most of the 13-kv distribution circuits will tend to have uniformly distributed load. To allow for the possibility of loading the last half of a circuit somewhat more than the first half, it is planned to use 397,500 CM for approximately one-half the distance out from the substation on the circuit. If the last half of a line is fairly uniformly loaded and decreases to a very small load at the end of the main line run, the combination of 266,800 CM and no. 2/0 should be used for the last half of the line. Approximately one-half of the distance should be used for each size. If the load distribution is spotty with several heavily loaded spurs taking off near the end of the main line section, only 266,800 CM should be used for the last half. In determining the ratio of 266,800 CM and no. 2/0 which should be used, some thought should also be given to possible rearrangement of the line in the future so that a large enough conductor will be available at that time.

Conclusions

This study has shown that the three sizes of no. 2/0, 266,800 CM, and 397,500 CM ACSR conductor can be standardized and used in combination for the most economical circuit design for the loads to be carried by the 13-kv distribution system. Graded construction will be used for all new main line constructions with 397,500 CM used for half the distance and the other half composed of 266,800 CM and no. 2/0 in ratios determined by conditions of load distribution. Voltage regulation on long lines with heavy loads will need voltage regulator installations and possibly capacitor bank installations to hold voltage drop within prescribed limits. However, only one set of each are needed on a 10-mile circuit with a maximum allowable uniformly distributed load of 6,000 kva to give satisfactory service.

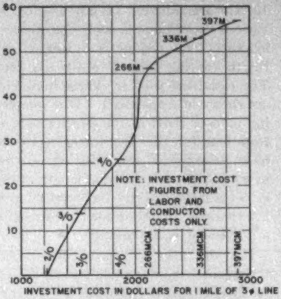

Fig. 3. Voltage-drop reduction gained per $ Invested for increasing ACSR distribution conductor size

Nomenclature

a_1 = ratio of large conductor length to total length
a_2 = ratio of medium conductor length to total length
K_1, K_2, K_3 = installed costs per mile of a 3-phase line (excluding poles and hardware) for large, medium, and small conductor respectively
L = length of circuit, miles
R = per-unit resistance
R_1, R_2, R_3 = per-unit resistance of conductors per circuit mile per 1,000 kva
I_1 = per-unit load in section
I_2 = per-unit load feeding through section
kva = initial load, kilovolt-amperes
n = number of years
r = rate of growth per year (as decimal)
C = annual cost
AC = accumulated annual cost

Appendix I. Equations for Determining Accumulated Annual Cost for Various Combinations of Conductor Sizes

Accumulated annual cost calculations were made for Fig. 2 using a circuit with graded construction and uniformly distributed load growing at a constant yearly rate. If three sizes of conductor are to be used, the following equations can be set up.

Losses for the last section are obtained using the well-known equation for uniformly distributed load where total losses are the same as if the total load were concentrated one-third of the distance out on the line. For sections where feed through of load must also be taken into account, the following equation gives the total losses for these sections

$$\text{Losses} = R(L)\left(I_2^2 + I_1 I_2 + \frac{I_1^2}{3}\right)$$

$$\text{Investment cost} = 0.155(L)[K_1 a_1 + K_2 a_2 + K_3(1 - a_2 - a_1)]$$

Loss cost

$$\text{1st section} = 0.032(R_1)(L)(\text{kva}^2)(a_1 - a_1^2 + a_1^3/3)$$

$$\text{2nd section} = 0.032(R_2)(L)(\text{kva}^2)[a_2(a_1 - 1)^2 + a_2^2(a_1 - 1) + a_2^3/3]$$

$$\text{3rd section} = 0.032(R_3)(L)(\text{kva}^2)[1/3 + a_1(a_2 - 1)^2 - a_1^2(a_2 - 1) - a_1^3 - (a_2 - a_2^2 - a_2^3/3)]$$

$$C = (\text{investment cost}) + (1+r)^{2n}(\text{loss cost}) \quad \text{for any year } n$$

and

$$AC = \int_{1/2}^{n+1/2} C\,dn$$

$$AC = n\,(\text{investment cost}) + \left(\frac{(1+r)^{2n+1} - (1+r)}{2 \log_e (1+r)}\right)(\text{loss cost})$$

To obtain the most economical (minimum cost) length for each conductor size, the following steps were made

$$\frac{dAC}{da_1} = 0 = \frac{dAC}{da_2}$$

Solving for a_2 using the two equations just obtained, substituting back, and taking $(dAC)/(da_1) = 0$

$$a_1 = 1 - \sqrt{\frac{9.7(n) \log_e (1+r)}{\text{kva}^2[(1+r)^{2n+1} - (1+r)]}} \times \sqrt{\frac{K_1 - K_2}{R_2 - R_1}}$$

Substituting back in one of the equations

$$a_2 = \sqrt{\frac{9.7(n) \log_e (1+r)}{\text{kva}^2[(1+r)^{2n+1} - (1+r)]}} \times \left(\sqrt{\frac{K_1 - K_2}{R_2 - R_1}} - \sqrt{\frac{K_2 - K_3}{R_3 - R_2}}\right)$$

then

$$a_3 = 1 - a_2 - a_1 = \sqrt{\frac{9.7(n) \log_e (1+r)}{\text{kva}^2[(1+r)^{2n+1} - (1+r)]}} \sqrt{\frac{K_2 - K_3}{R_3 - R_2}}$$

For construction using two sizes of conductor

$K_3 = 0$

$R_3 = \infty$

a_1 = same as before

$$a_2 = \sqrt{\frac{9.7(n) \log_e (1+r)}{\text{kva}^2[(1+r)^{2n+1} - (1+r)]}} \times \sqrt{\frac{K_1 - K_2}{R_2 - R_1}} = 1 - a_1$$

For construction using 397,500 CM, 266,800 CM, and no. 2/0, the proportions of each size of wire is determined as follows

$$a_1=1-\sqrt{\frac{9.7(10)\log_e 1.116}{(2{,}000)^2(1.116^{21}-1.116)}}\times\sqrt{\frac{2{,}882-2{,}114}{0.00221-0.00149}}$$

$$=0.444$$

$$a_2=\sqrt{\frac{9.7(10)\log_e 1.116}{(2{,}000)^2(1.116^{21}-1.116)}}\times\left(\sqrt{\frac{2{,}882-2{,}114}{0.00221-0.00149}}-\sqrt{\frac{2{,}114-1{,}229}{0.00513-0.00221}}\right)$$

$$=0.26$$

$$a_3=1-0.444-0.26=0.296$$

where

K_1 = \$2,882 per mile installed cost of 397,500 CM
K_2 = \$2,114 per mile installed cost of 266,800 CM
K_3 = \$1,229 per mile installed cost of no. 2/0
R_1 = 0.00149 per unit, ohms per 1,000 kva per mile
R_2 = 0.00221 per unit, ohms per 1,000 kva per mile
R_3 = 0.00513 per unit, ohms per 1,000 kva per mile
kva = 2,000 kva initial load
r = 11.6 per cent per year growth
n = 10 years

◆

Discussion

J. A. Salin (Ebasco Services, Inc., New York, N. Y.): The authors are to be congratulated on a very well written and well-presented paper. I think it is clear and very much to the point. I have compared the conductor sizes indicated to be most economical for the loads considered against similar studies that my associates and I have made and I find that within these load limits they are in substantial agreement. This is rather surprising, however, because it is our feeling that complete line costs should be used in economical wire size studies rather than the cost of conductor alone or incremental costs. I think it would be interesting to know why the authors feel that the cost of structures should be left out altogether.

As indicated in the paper, application of results is very important and, in using the results of any study, consideration must be given to the many factors which cannot be accurately evaluated in dollars. In this connection, why stop at the 397,500 CM conductor? While supporting structure costs may increase for conductor sizes larger than 397,500 CM, the increase may and usually is more than offset when the alternates such as additional line construction and perhaps even additional substations and/or transmission lines are required. Increase in pole-line costs for conductors up to 800,000 CM all aluminum on short-span construction is not great. I mention the use of conductor sizes greater than 397,500 CM because, while load densities in the area considered by the authors may not indicate circuit loads in excess of 6,000 kva, greater densities, which are becoming quite common, result in economical 13-kv circuit loads well in excess of 6,000 kva.

I am not certain whether reference to no. 2/0 ACSR as a minimum size applies to laterals or not. If so, I believe smaller conductors should be considered (say for loads under 40 amperes) as savings in investment in laterals are important since they make up a large part of the total investment in primary lines.

If conductor sizes larger than 397,500 CM and smaller than no. 2/0 are used I feel the two sizes 397,500 and 266,800 CM could be reduced to one size only. The conditions and practical considerations mentioned by the authors are certainly very important and, though it is difficult to bring them into the economical calculations, I feel they should have considerable bearing on the selection of wire size. One practical point upsetting the conclusions is that many circuits are not long radials with evenly distributed loads as were used in the analysis. Frequently, and this is an advantage from the standpoint of voltage drop and losses, circuits break up into two or more branches near the source. Another point is that circuits must be designed for emergency as well as normal operation and, while greater voltage drop and losses can be tolerated under emergency operation, ties to other circuits for emergency purposes must be adequate to perform satisfactorily when needed. Also, as the system grows, more substations will be added, and long-range plans should be carefully prepared to prevent, in so far as practical, needless and expensive conductor replacements at a later date.

J. R. Oberholtzer (Commonwealth Associates Inc., Jackson, Mich.): This paper presents an excellent analysis of the effect of proper consideration of the cost of distribution losses on system design. In the postwar era of rapid expansion, these losses have often been overlooked, sometimes necessarily so because of lack of manpower and material. The constant recognition of losses should be a part of any system-planning procedure.

It is significant to compare the current ranges for static loads for various conductor sizes, shown in the section entitled "Economic Comparison for Static Loads," with the thermal ratings of these conductors. For the first three, the maximum current is only about 20 per cent of the thermal rating. Referring to Fig. 2, the maximum load through a conductor, under conditions of growing load distributed along the line, is shown to be less than half the thermal limit for economical application.

Referring again to Fig. 2, it is noted that the use of the larger conductor to a greater extent than indicated for minimum cost will increase the accumulated annual costs only slightly. Decreased voltage drops resulting from greater use of the larger wire are not evaluated in this comparison and would tend to favor the larger size. Also, the percentage fixed-charge difference would probably be smaller if the comparison were extended over the entire life of the circuit, since loading after the first 10 years would probably be nearer the circuit rating. Considering these items, it appears that preference should be given to the largest conductor if there is any reasonable expectation that the line will become a trunk feeder to a load concentration or from a future 13-kv source. It seems that the direct route between two initial sources should have the largest conductor size throughout its length.

Although the load density in the area under consideration is not stated, the circuit dimensions indicate that it is rather light compared to the usual urban densities. Even at these light densities, adequate primary voltage is provided by one set of line regulators installed on each circuit. Considering the application of this distribution voltage at greater densities, in the order of 1,000 kva per square mile, it appears that both thermal limits and primary voltage drop will disappear as design limitations to be replaced by power loss considerations.

A. W. Funkhouser and R. P. Huber: The authors appreciate the comments of Mr. Salin and Mr. Oberholtzer which should add to the value of the paper. It is interesting to note that both discussers agree that more extensive use of larger conductor sizes for distribution systems is in order. It has been our experience in the past that wire sizes have been chosen conservatively and at times do not fit in with future requirements. They can become obstacles to good design since change-out costs often cannot be justified on the basis of economics.

Mr. Salin questions the omission of pole and hardware costs. Since our study is a comparison between sizes based on relative annual cost, any fixed charges common to all will not affect the relative position of the cost curves. For reasons set out in the text, the costs of poles and hardware would not vary on our particular system for the range of sizes considered. This permitted us to leave them out of our study.

The suggestion that greater circuit loadings and considerably larger conductor sizes might be used would be applicable, we feel, in areas with greater initial load density and greater load growth rates (approximately 100 kva per square mile and 11.6 per cent in this study) and on systems requiring considerably more new pole-line construction than was necessary in our system. Our study was limited to main line construction and, as suggested by Mr. Salin, smaller conductors will be used for laterals. At present, most existing laterals have no. 4 copper which will remain, and for new construction no. 2 ACSR will be used.

The point that the forking of a feeder circuit near the source might alter the selection of conductor sizes is well taken, but such an arrangement would be exceptional in the area studied. The method of conductor grading might still be applicable to the main branches, depending upon the permanency of the forked arrangement.

We agree with Mr. Salin that the emergency capabilities must be considered to make sure that the sizes selected are adequate from the thermal- and voltage-regulation standpoint. With the size of economical conductor being substantially above thermal limitations, as brought out by Mr. Oberholtzer, the capacity of the conductor should be sufficient in most cases. With a line-section voltage-regulation limitation of $4^{1}/_{2}$ per cent, considerable additional emergency load can be carried before a critically low voltage is reached.

As pointed out by Mr. Oberholtzer, the recognition of distribution losses is an important factor in system design. If the circuits are allowed to remain loaded up to maximum load in future years, the losses will be the predominant factor and would favor the use of larger conductor. We think that when maximum circuit loads are reached additional circuits or rearrangements with new substations will tend to repeat the load-growth cycles on feeder sections, although possibly not over as great a range as the original assumption of a 3 to 1 ratio of final to initial load. The process of adding substations and reducing circuit length as load densities grow will increase the importance of losses as compared with the thermal- and voltage-drop limitations in the selection of conductor sizes.

Distribution-Substation and Primary-Feeder Planning

W. J. DENTON
ASSOCIATE MEMBER AIEE

D. N. REPS
ASSOCIATE MEMBER AIEE

ELECTRIC utility distribution system planning is extremely difficult because plans for the addition of new facilities must keep well ahead of the time when the exact locations and magnitudes of the future loads to be served by those facilities are known. This paper presents a basis and methods for distribution system planning which take load growth into account in such a way that exact locations and magnitudes of future loads need not be known to arrive at an economic system for serving the loads when they develop. To accomplish this purpose, hypothetical, equivalent distribution systems are devised for quickly analyzing the service quality and the economic feasibility of distribution system growth plans applicable to the load areas of the actual system being studied.

The system planning concepts and methods presented in this paper are particularly applicable to urban and suburban residential areas, served predominately by overhead circuits. In such load areas some of the most fundamental planning problems center on the distribution substations, where the interrelated problems of subtransmission-system and primary-feeder design converge. Choice of distribution-substation arrangement, size, and voltage rating influences system planning in two directions: toward the source via the subtransmission circuits, and toward the load via the primary-feeder circuits.

The equivalent-system method recognizes the uncertainty of the exact magnitudes and locations of future loads in planning the locations and ratings of distribution substations, and the number and capability of the primary feeders required to distribute the power from these substations. In the equivalent system each distribution substation with its primary-feeder circuits serves an area in which load density is comparable to the values existing or forecast for the actual system being studied. Results of studies made for equivalent systems, for different values of load densities, are applicable to actual systems despite wide variations in the actual locations of individual loads in the equivalent or actual system.

Hypothetical, Equivalent Substation Areas

The hypothetical, equivalent distribution-substation areas employed in the analyses of this paper have the shape of regular polygons. The number of sides to the polygon representing a load area is equal to the number of primary feeders radiating from the primary-circuit feed point, which is assumed to be located at the center of the area. The distribution substation may be located at the feed point, or may be remotely located, with one or more express primary feeders carried from the remote substation to the feed point. For example, a hypothetical area served by six circuits radiating out from a feed point would be hexagonally shaped, with each feeder carried from the center of the hexagon along an apothem, or diagonal.

The use of hypothetical load areas and circuit patterns of symmetrical geometry greatly simplifies the comparison of alternative plans which may call for different sizes of distribution substation, different numbers of primary-feeder circuits, and different primary-feeder voltages. Such load areas and circuit patterns are abstractions because they do not exist exactly in such forms anywhere. These abstractions, however, can be made to conform with the system they are devised to represent in all of the following ways: load density, substation size; substation or feed-point service area in square miles; number of primary-feeder circuits; conductor material, and circuit impedance values; and primary-feeder voltage.

Hypothetical distribution-substation areas cannot be made to conform with actual systems in two ways: the exact duplication of circuit pattern, and the exact locations and magnitudes of loads. But as load grows, these two attributes of the system continually change, sometimes at so fast a rate that the system planner must spend all of his time with remedial measures or extensions in relatively small portions of the system, while the possibilities for system-wide engineering and economic benefits go uninvestigated.

Distribution-Substation Planning

The one phenomenon common to all distribution-system load areas is increasing load density. This is particularly true of the urban and suburban residential areas served by overhead primary-feeder circuits. Regardless of the plan adopted for serving such areas, load growth must be accompanied by (perhaps should be preceded by) an equivalent increase in distribution-substation and primary-feeder capacity. Very often, to achieve the required increases in system capability, changes in the basic system-growth plan must be made.

There are many features of the distribution substations and primary feeders that can be changed, over any reasonable

Paper 55-158, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31-February 4, 1955. Manuscript submitted October 26, 1954; made available for printing December 2, 1954.

W. J. DENTON is with the Westinghouse Electric Corporation, Des Moines, Iowa, and D. N. REPS is with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

period of time, provided that the funds required for making the changes are available and that continuity of service to the customers is maintained while the system is being altered or expanded. Indeed, many changes are very desirable and serve to improve system economy, quality of service, and operation. Such changes may affect all of the following: primary-feeder voltage; distribution-substation size and arrangement; number of, and routing of, primary-feeder circuits; primary-feeder loading; the various applications of supplementary voltage regulators, switched and unswitched capacitors, line-sectionalizing devices, etc. Any change must eventually lead to an increase in distribution-substation capacity.

The addition of distribution-substation capacity can follow virtually an infinite variety of general plans which must fall, however, between two extremes. In one extreme, the area served from a single substation site remains fixed and the capacity of the substation grows with load density. In the second extreme, a fixed amount of transformer capacity is located on a given substation site and additional transformer capacity is located at new sites as load grows. These two extremes of distribution-system growth will be called:

1. The constant substation-area plan.
2. The constant-substation-size plan.

Between two extremes there are an infinite variety of plans which call for both the enlarging of existing substations and the addition of new substations.

As load grows, the evolution of distribution substations and primary feeders may proceed slowly at certain times, and rapidly at other times, depending on what steps are taken. Changes which occur rapidly may be embodied into the system before the load has increased by very much. During changes which evolve slowly, the load may increase appreciably.

The rate of load growth, with the attendant system-wide increase of load density, will vary not only from one system to another but also within individual substation areas. The engineering and economic factors determining the capability and pattern that a system should have at any given time depend on the rate of load growth, which unfortunately is at times a highly uncertain factor. Consequently, in order to base a system plan on some limits within which the uncertainties of load growth will lie, the various steps that can be taken to increase distribution-substation and primary-feeder capacity can be divided into two general categories: those which are accomplished while the load density remains constant, and those which are achieved usually over considerably longer periods of time during which the load density increases. The accuracy of load growth forecast will determine the accuracy of the estimated time period over which such changes should be made.

For short-range planning, the assumption can be made that load density remains constant. Even for short-range planning, however, any analysis which freezes load density will be recognized as not realistic, since load density in some urban and suburban residential areas increases appreciably even during time intervals measured in months. But a constant-density analysis, though it is academic, does serve the useful purpose of establishing certain limits on what can be accomplished when certain types of changes are made.

Nomenclature

D=load density, kilovolt-amperes (kva) per square mile
n=number of primary-feeder circuits emanating from a distribution substation site, or primary feed point. Referred to as an n-feeder pattern
kva_n=kva loading per feeder in an n-feeder pattern
kva_{nt}=total kva loading for all n feeders in an n-feeder pattern
A_n=area in square miles served by one primary feeder in an n-feeder pattern
A_{nt}=total substation or feed-point area in square miles served by an n-feeder pattern
S=radius, or opothem, of a regular polygon representing an area served by n feeders
kv=voltage at which a primary feeder operates
V_{ab}=per-cent (%) voltage drop from point a to point b
K_M=% voltage drop per kva-mile in a primary-feeder main
K_F=% voltage drop per kva-mile in a primary subfeeder
K_L=% voltage drop per kva-mile in a primary lateral
$K_1, K_2, a, b, c, d, e, a', b', c', p, q, x, y, \theta, u, v, w, P_n$ are all used in connection with particular derivations and are not intended for general use

System Changes at Constant Load Density

System planning often is centered about remedial measures which are required because of inadequate capability in the existing distribution substations and primary feeders, or poor quality and continuity of service. Usually when distribution substations and primary-feeder circuits are inadequate from a load-carrying capability standpoint, voltage drops are excessive and outages are frequent and of long duration.

Some of the obstacles that may be encountered in attempting to achieve short-range remedies, with long-range continuing benefits, are: unavailability of new substation sites and subtransmission and primary-circuit easements; prohibiting ordinances or codes or unfavorable civic sentiment toward more numerous or higher voltage circuits; and insufficient funds for investment in new facilities.

Two basic types of changes to distribution substations and primary feeders will be examined while load density remains constant: those involving an increase in primary-feeder voltage, and those for which primary-feeder voltage remains the same. Figs. 1 through 5 picture five different plans for the changing of distribution-substation size and area, or the number of primary feeders, at constant load density. Figs. 1, 2, and 3 deal with feeder-voltage increase. Figs. 4 and 5 show what can be done through two remedial measures applied at the existing primary-feeder voltage. Hypothetical substation areas having the shape of regular polygons are used to demonstrate the effects of these changes.

CONSTANT LOAD DENSITY—INCREASING PRIMARY-FEEDER VOLTAGE

Figs. 1, 2, and 3 illustrate a type of system renovation that has achieved considerable popularity—increasing the primary-feeder voltage. When such an extensive and high conversion cost project is undertaken, there are certain factors which govern what can be accomplished. It is well known that for the same kva loading the % voltage drop in a primary-feeder circuit will decrease inversely with the square of the voltage. A new voltage three times the original voltage will result in one-ninth the original % voltage drop. But when primary-feeder voltage is increased, optimum benefits may accrue if feeder loading, or distribution-substation size, is allowed to increase, at some sacrifice to the maximum possible reduction in feeder % voltage drop. Figs. 1, 2, and 3 each describe a possible plan for increasing primary-feeder voltage.

Fig. 1: At constant load density, constant substation size (and area), and constant % voltage drop per feeder, the number of primary feeders varies inversely as the square of the primary-feeder voltage. The following relationship describes this effect.

$$n \propto \left.\frac{1}{kv^2}\right|_{\text{Constant } D, kva_{nt}, A_{nt}, V} \tag{1}$$

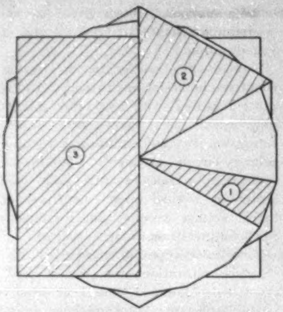

Fig. 1. Constant D, kva$_{nt}$, A$_{nt}$, V. The number of primary feeder varies as shown in equation 1. Relative values of primary-feeder voltage are:

1. kv=1.0; 2. kv=1.73; 3. kv=3.0

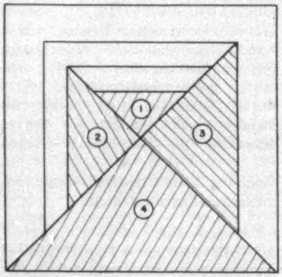

Fig. 2. Constant D, n, V. The substation loading or service area varies as given by equation 2. Relative values of primary-feeder voltage are:

1. kv=1.0; 2. kv=1.73; 3. kv=3.0; 4. kv=5.0

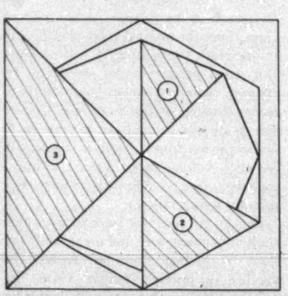

Fig. 3. Constant D. The substation loading, number of feeders, and primary-feeder voltage vary as shown by equation 3. Relative values of primary-feeder voltage are:

1. kv=1.0; 2. kv=1.73; 3. kv=3.0

Figs. 1 through 9. The regular polygons represent areas that are served from a distribution substation or feed point located at the center of the concentric polygons. The shaded sectors represent the area that can be served by one primary-feeder circuit emanating from the feed point or substation. The circled numbers with the shaded feeder-sector areas refer to the relative value of the planning parameter that is varied for that type of plan represented by the particular figure. The system-planning parameters are: Load density D; substation or feed-point loading kva$_{nt}$; substation or feed-point service area A$_{nt}$; primary-feeder voltage kv; number of primary feeders radiating from the feed point n; % voltage drop from the feed point to the end of the primary-feeder circuit V

In Fig. 1 hypothetical distribution-substation areas employing three relative values of voltage are illustrated: 1.0 kv, 1.73 kv, and 3.0 kv, with 18, 6, and 2 primary feeders required at these voltages respectively.

Fig. 2: If for an increase in primary-feeder voltage the number of primary feeders radiating from a substation or feed point remains the same, and the total % voltage drop per feeder remains the same, then each feeder can serve a larger area at the same load density. Fig. 2 illustrates that for a constant number of feeders, and % drop, at constant load density the area served by each feeder varies as the voltage raised to the four-thirds power

$$kva_{nt} \propto A_{nt} \propto kv^{4/3}\Big|_{\text{Constant } D,n,V} \qquad (2)$$

In Fig. 2 the relative areas that can be served by primary feeders operating at 1.73, 3.0, and 5.0 times the original kilovolts of relative value 1.0 are shown.

Fig. 3: Substation-revision plans provide for maximum benefits in reducing the number of feeders, Fig. 1, or increasing the substation size using the same number of feeders, Fig. 2, through the use of a higher primary-feeder voltage. However, optimum economic and service-quality benefits attendant with changeover to a higher primary-feeder voltage can usually be realized if use of the same, or somewhat fewer, primary feeders is accompanied by use of a larger distribution substation. An increase in primary-feeder voltage could result in a substation-area pattern which falls somewhere between the extremes of Figs. 1 and 2. Such a change is shown in Fig. 3.

With changeover to a higher primary feeder voltage, three results can be achieved: reduction in the number of feeders; increased substation size; reduction in the feeder % voltage drop. The extent to which all these desirable benefits can be accomplished simultaneously is given by the following relationship

$$V \propto \frac{kva_{nt}^{3/2}}{n^{3/2}kv^2}\bigg|_{\text{Constant } D} \qquad (3)$$

Fig. 3 shows changes to higher primary-feeder voltages while the % voltage drop in feeders remains constant. When the existing primary-feeder voltage is multiplied by 1.73, the number of feeders can be reduced by 25% (from eight to six in this case), while the substation size can be increased by 33%. With a changeover to three times the original primary-feeder voltage, the number of primary feeders can be reduced to half (from eight to four in this case) and substation size may be doubled.

If, however, some reduction in feeder % voltage drop is also desired when the

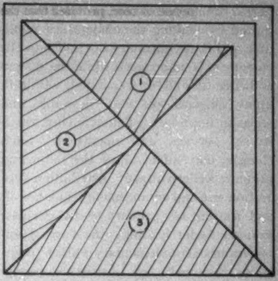

Fig. 4. Constant D, kv, n. The substation or feed-point loading and service area vary as shown by equation 4. Relative values of primary-feeder % voltage drop are:

1. V=1.0; 2. V=2.0, 3. V=3.0

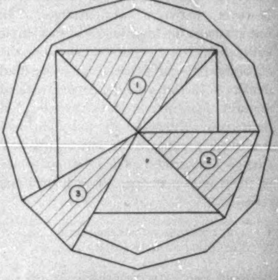

Fig. 5. Constant D, kv, V. The substation or feed-point loading and number of primary feeders vary according to the relationship in equation 5. Relative values for substation or feed-point loading are:

1. kva$_{6t}$=1.0; 2. kva$_{9t}$=1.5; 3. kva$_{12t}$=2.0

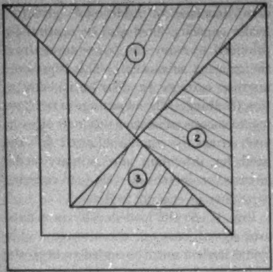

Fig. 6. Constant kva_{nt}, n, kv. As load density increases while substation load remains constant, substation or feed-point service area and % voltage drop in feeders vary as given by equation 6. Relative values of density, area, and % voltage drop are:

1. $D=1.0$, $A_{nt}=1.0$, $V=1.0$
2. $D=2.0$, $A_{nt}=0.5$, $V=0.7$
3. $D=4.0$, $A_{nt}=0.25$, $V=0.5$

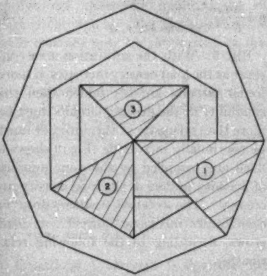

Fig. 7. Constant kva_{nt}, V, kv. As load density increases while substation load remains constant, the number of primary feeders and substation or feed-point area vary as given by equation 7. Relative values of density, area, and % voltage drop are:

1. $D=1.0$, $A_{nt}=1.0$, $V=1.0$
2. $D=2.0$, $A_{nt}=0.5$, $V=1.0$
3. $D=4.0$, $A_{nt}=0.25$, $V=1.0$

changeover is completed, then the substation-size increases cannot be as great as shown for Fig. 3, which illustrates constant % voltage drop cases. The changes illustrated in Fig. 3 are not intended to represent optimum engineering and economic improvement but only serve to illustrate what may, or may not, be accomplished with changeover to a higher primary-feeder voltage.

CONSTANT LOAD DENSITY—UTILIZING THE SAME PRIMARY-FEEDER VOLTAGE

Figs. 4 and 5 illustrate changes in substation size and the primary-feeder pattern while maintaining the same primary-feeder voltage. Such changes do not usually require the numerous, high initial cost system renovations which must accompany a changeover to a higher primary-feeder voltage.

At a constant load density, with the use of the existing primary voltage, an increase in the distribution-substation capacity at a given site can be accomplished only by increasing the number of primary feeders or increasing the loading, and consequently the % voltage drop, in the existing feeders.

Fig. 4: An increase in feeder loading at constant load density, with the attendant increase in % voltage drop in each feeder, is illustrated in this picture of a hypothetical, 4-feeder substation. An increase of 60% in feeder loading results in twice the original % voltage drop, and an increase of 110% in feeder loading results in three times the original % voltage drop. The following relationship describes this

$$kva_{nt} \propto A_{nt} \propto V^{2/3}\Big|_{\text{Constant } D,\, kv,\, n} \qquad (4)$$

An increase in % voltage drop must ordinarily be compensated for by an increased use of supplementary forms of primary-feeder voltage regulation, so that the voltage spread allocated to the primary-feeder circuit does not become excessive. Thus if the total drop is increased, additional voltage regulators must be installed at points the primary feeder so that the drop between voltage-regulated points, or between the last point on the line at which a regulator is applied, and the end of the feeder does not exceed the allowable spread-governed voltage drop in the primary feeder.

Fig. 5: A method for increasing the substation capacity at a given site, with the same primary-feeder voltage and % voltage drop in feeders, is to increase the number of feeders. The expression for this type of change is approximately given by

$$n \propto \frac{kva_{nt}}{\tan^{1/3}\left(\dfrac{180}{n}\text{ degrees}\right)}\Bigg|_{\text{Constant } D,\, kv,\, V} \qquad (5)$$

In equation 5 it will be noted that the tangent of half the angle represented by a feeder "sector" is included in the relationship. Thus the variation of kva_{nt} with n will depend to a considerable extent on the particular values of n employed before and after the change.

A typical example is shown in Fig. 5. In this case of feeder addition at constant load density and % drop, an increase from four to eight feeders permits a 50% increase in substation size. Tripling the number of feeders, from 4 to 12, permits the approximate doubling of substation size.

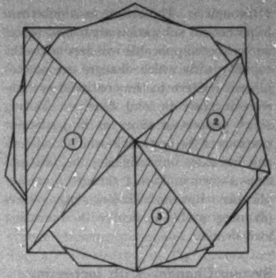

Fig. 8. Constant A_{nt}, V, kv. As load density increases while substation or feed-point area and % voltage drop in feeders remain constant, the relationship between the variable system-planning parameters is given in equation 8. Relative values of density, number of primary feeders, and % voltage drop are:

1. $D=1.0$, $n=4$, $V=1.0$
2. $D=2.0$, $n=7$, $V=1.0$
3. $D=4.0$, $n=10$, $V=1.0$

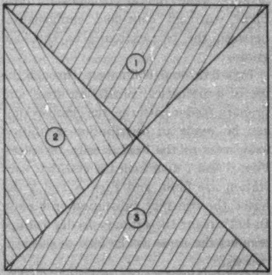

Fig. 9. Constant A_{nt}, n, kv. As load density increases while substation or feed-point area and number of feeder circuits remain constant, the relationship between the variable system-planning parameters is given in equation 9. Relative values of density, number of primary feeders, and % voltage drop are:

1. $D=1.0$, $n=4$, $V=1.0$
2. $D=2.0$, $n=4$, $V=2.0$
3. $D=4.0$, $n=4$, $V=4.0$

SUMMARY FOR CONSTANT LOAD-DENSITY CHANGES

The relationships between the substation size and the primary-feeder circuit pattern as changes are made at a constant load density have been pictured in Figs.

1 through 5. The extent to which these hypothetical substation areas and feeder patterns are applicable will depend on the rapidity with which changes are accomplished relative to the continual systemwide increase in load density. During short periods of time, or in particular portions of the system, in which load density increases only slightly, the relationships shown in Figs. 1 through 5 are applicable. But the basic long-range system planning problems deal with increasing load density.

System Changes With Increasing Load Density

Two extreme plans for making system changes at increasing load density—one calling for constant substation size, and the other for constant substation area—have already been discussed. Neither type of plan permits obtaining the maximum possible benefits in all components of the distribution system. A long-range optimum plan for any specific system will generally be one in which the system will acquire some of the benefits of both plans, through continual compromises between the two extremes as the load grows.

Figs. 6 through 9 illustrate, through the use of hypothetical substation areas and primary-feeder patterns, the changes that can be made in distribution-substation load areas as the load density increases. Figs. 6 and 7 deal with the constant substation-size plan, and Figs. 8 and 9 describe the constant substation-area plan. In both plans the primary-feeder voltage remains the same as the load density increases.

INCREASING LOAD DENSITY—CONSTANT SUBSTATION-SIZE PLAN

If the amount of capacity located at any one substation site remains fixed as the load density increases, then increments of new substation capacity that are continually added must be placed at new sites geographically located at points lying between existing substations. As load density increases, substation area decreases, so as to keep substation loading constant. The principal disadvantage of such a plan is that, as the load grows, suitable substation sites may not be obtainable. However, as one extreme representing a limit within which system growth must take place, this plan merits attention.

Constant substation-size plans may in turn be grouped into two basic schemes. In one, the number of primary-feeder circuits remains constant with increasing load density, but the % voltage drop is high at the outset when the load density is light and the substation area is relatively large. In the second scheme, primary-feeder voltage drop remains constant with increasing load density, requiring the use of more feeders per substation at the outset, when the density is low and the feeder circuits are long. These two schemes are shown in Figs. 6 and 7.

Fig. 6: With increasing load density, the use of a constant number of primary-feeder circuits supplied from a substation of constant size results in a continually decreasing % voltage drop in feeder circuits as the substation area decreases and the primary feeders are shortened. The following relationship describes this behavior

$$V \propto \frac{1}{D^{1/2}} \propto A_{nt}^{1/2} \Big|_{\text{Constant } kva_{nt},\, n,\, kv} \qquad (6)$$

In Fig. 6, when the load density in the area served by a constant-size substation has doubled and substation area is halved, voltage drop is reduced to 70% of its original value. When load density in the still further reduced substation area is four times the original value, the % voltage drop is reduced to half the original amount.

Fig. 7: With increasing load density and constant substation size, constant % voltage drop in primary feeders can be kept constant while the required number of feeders per substation continually decreases. Thus construction of new feeder circuits can proceed at a slower rate than substation addition. The number of feeders per substation, as a function of load density, is given by

$$n \propto \frac{1}{D^{1/2}} \propto A_{nt}^{1/2} \Big|_{\text{Constant } kva_{nt},\, V,\, kv} \qquad (7)$$

In Fig. 7, when the load density is doubled, the number of primary feeders required to serve the smaller area containing the same load is reduced from eight to six. When load density is quadrupled, the number of feeders is reduced to four. Note that the need to always consider a whole number of primary feeders will require use of the nearest, larger whole number of feeders if the value for n given by equation 7 does not result in a whole number.

INCREASING LOAD DENSITY—CONSTANT SUBSTATION-AREA PLAN

If the size of the area served from a given substation site remains constant as the load density increases, then additional transformer capacity must be placed at that site as the load within the area increases. Additional primary-feeder capacity must also be continually provided to carry the power away from the growing substation. This represents another extreme in distribution-substation planning. The advantage of not having to locate substations at new sites as load grows is counterbalanced by the need for providing new primary-feeder circuits or increasing the load-carrying capability of existing feeders.

Fig. 8: As the load density in a fixed area served from one site increases, additional feeders must be added to keep the % voltage drop in the feeder circuits constant. In the case shown in Fig. 8, when load density and substation load have doubled, the number of primary feeders increases from four to seven. At four times the original load density, ten primary feeders are required. The relationship between the number of feeders and the substation size for the constant-area plan is given approximately by

$$n \propto \frac{kva_{nt}}{D^{1/2}} \Big|_{\text{Constant } A_{nt},\, V,\, kv} \qquad (8)$$

Fig. 9: With the substation area constant as the load density increases, if more feeder circuits are not added then the capability of the existing circuits must be more than adequate at the outset or must be continually increased. Fig. 9 shows a fixed area supplied by the same number of primary feeders as the load density increases. The total % voltage drop in each feeder increases, however, as load grows, according to the following relationship

$$V \propto kva_{nt} \propto D \Big|_{\text{Constant } A_{nt},\, n,\, kv} \qquad (9)$$

The capability of a constant number of feeders serving a constant area as the load density increases is limited in two ways: one limit is the thermal capability of the feeder conductors, and the other is the maximum allowable % voltage drop between voltage regulated points on the feeder circuit. Provided that the existing feeder conductors are of adequate size to carry the load current, supplementary voltage regulators can be added along the feeders as load grows. Although the total voltage drop continually increases, this practice would keep the voltage spread along the feeders from becoming excessive.

CHANGES IN PRIMARY-FEEDER VOLTAGE WITH LOAD DENSITY INCREASING

Long-range system planning problems always involve increasing the load densities. Often, such planning may consider increases in the primary-feeder voltage. The increasing density examples of Figs.

6 through 9 are based on unchanged primary-feeder voltage. The effects of increased primary-feeder voltage with increasing load density can be obtained by combining the plans of Figs. 1, 2, and 3 with any one or more of those in Figs. 6 through 9. Such a procedure is one which "freezes" the load density at several values, each larger than the preceding density. The effects of various plans can then be observed from one value of load density to the next. This technique of observing dynamic or growth situations through a number of successive static representations is a standard procedure in fields of endeavor as widely diverse as power-system stability, economic theory, motion pictures, and theoretical physics.

Planning for Specific Systems or Areas

The various changes by which distribution substations and primary feeders evolve are described qualitatively in Figs. 1 through 9. The plans calling for such changes may be catalogued as follows:

1. Constant load-density planning
   a. Increasing primary-feeder voltage, Figs. 1, 2, and 3
   b. Unchanged primary-feeder voltage, Figs. 4 and 5
2. Increasing load-density planning
   a. Constant-load distribution substations, Figs. 6 and 7
   b. Constant-area distribution substations, Figs. 8 and 9

Equations 1 through 9 describe the qualitative relationships between load density, substation size and service area, number of primary feeders, primary-feeder voltage, and feeder % voltage drop for Figs. 1 through 9 respectively. The equations are gleaned from the results of the derivations presented in the Appendixes. Since these equations deal with the physical and electrical attributes of the distribution system, substitution of wide ranges of practical values for these parameters into the more complete equations of the Appendixes yields information that can be used for the planning of specific systems. Typical results of such substitutions into the equations are shown in Figs. 16 and 17. All of the system-planning factors enumerated in the foregoing, are represented quantitatively in Figs. 16 and 17. From these figures the growth of a specific system following any one of the plans can be observed.

Figs. 16 and 17 are, essentially, plots showing the number of primary feeders n per substation or feed point versus load density D within the substation or feed-point service area. The variation of n with D is shown for constant substation or feed-point loading kva_{nt} or constant substation or feed-point area A_{nt}. Fig. 16 deals with a primary-feeder voltage of 2,400/4,160 volts. Fig. 17 shows the relationships between the planning factors at 7,620/13,200 volts primary-feeder voltage. Each set (frame) of curves represents a different total % voltage drop in primary feeders. Curves for 3, 6, and 10% voltage drop are shown.

The system-planning factors, namely D, kva_{nt}, A_{nt}, n, kv, and V, may be followed by using these curves while one or more of the factors is kept constant or allowed to vary. The interrelated changes in magnitude or quantity of the six parameters are given in Figs. 16 and 17. An important system-planning ingredient not included in these relationships is time. During intervals of time over which load density increases little in certain portions of the system, the constant-density approach may be adopted for making changes. In other portions of the system, or over other periods of time during which load and density grow appreciably, the increasing-density plans may be applied.

Summary and Conclusions

Useful methods for distribution-substation and primary-feeder planning are given in this paper. The planning methods are based on the concept that actual distribution systems can be represented by hypothetical systems which are relatively simple to construct and analyze. For the purposes of system planning, these hypothetical systems are equivalent to the actual system which they represent.

Analysis of a number of primary-feeder circuit patterns of different geometric arrangement shows that distribution-substation and primary-feeder planning based on such circuit patterns are applicable to actual distribution systems. Although the ultimate locations and magnitudes of future loads will shape the growth of every distribution system, they cannot be ascertained far enough in advance to permit the exact determination of the distribution-system facilities required to serve these loads.

The exact locations of individual loads in urban-suburban areas need not be considered in studying the interrelated effect of the system planning parameters, which are the load density, distribution-substation size, primary-feeder voltage, number of feeders per substation and allowable voltage drop in feeder circuits.

The study of equivalent systems brings out the reasons for and the nature of the compromises that must be made in distribution-system design. Several plans for changes in the distribution -substation size, number of primary-feeder circuits, and feeder loading, as the load density remains constant or increases, are shown in Figs. 1 through 9. The construction of these hypothetical substation areas simplifies evaluating the effects of changes made in actual distribution systems. The quantitative relationships between the system-planning parameters are derived and are illustrated in the generalized curves of Figs. 16 and 17. These relationships can be used for quickly analyzing the service quality and economic feasibility of planning alternatives or proposed system changes.

Appendix I. Measures of Primary-Feeder Circuit Capability

In distribution-substation planning, another system component that is closely related to the substation is the primary-feeder circuit. Primary-feeder planning and design is in turn influenced not only by circuit load-carrying capability but also by the contribution that the primary feeders can make toward the quality of service, and continuity of service, rendered by the system as a whole. Because it is impossible to arrive at an optimum economic plan for distribution-system growth without specifying the quality of service to be rendered to the consumers, the primary-feeder circuits, with their contribution to both system capability and service quality, constitute a most vital part of system planning.

One very important measure of service quality is voltage spread. Voltage spread can be defined as the maximum difference in the magnitudes of the utilization voltages to which the appliances of all consumers on the same feeder circuit are subjected. In specifying the voltage spread not to be exceeded by a given distribution system design, a maximum allowable % voltage drop between voltage-regulated points is assigned to the primary-feeder circuits. This % voltage drop is determined, at maximum load, by the difference in the magnitudes of the voltages applied at the high-voltage terminals of the distribution transformers located most remotely (electrically) from each other on a section of primary-feeder circuit between voltage-regulated points.

The % voltage drop in primary-feeder circuits can be calculated to any degree of accuracy desired, but because of the continual change in load and the uncertainty of the exact load at any time an approximate method is generally used. In one such approximate method the voltage drop, actually defined as the arithmetic difference in the phasor voltages at two points, is assumed to be equal to the difference between the in-phase components of the phasor voltages at those two points. For

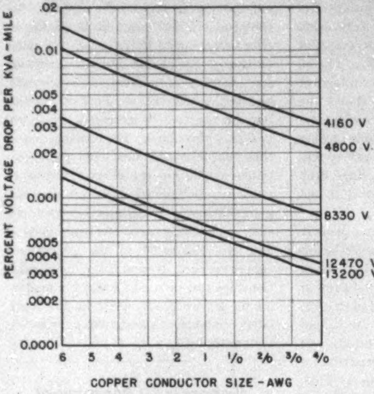

Fig. 10. % voltage drop per kva-mile for the popular copper conductor sizes. 3-phase open-wire lines with an equivalent spacing of 37 inches between phase conductors. Load power factor is 90%

a primary-feeder circuit on which one or more voltage regulators are applied, the total voltage drop in that feeder is defined, for the purposes of this paper, as the arithmetic sum of the voltage drops in each of the sections of feeder circuit between voltage regulators and between the last regulator and the end of the line.

When the operating voltage, impedance constants, and load power factor of a circuit are specified, then the total % voltage drop incurred by the load current carried in that circuit can be approximately expressed in terms of the product of kva and miles. Fig. 10 shows a plot of % voltage drop per kva-mile versus conductor size for open-wire copper-conductor primary-feeder circuits operating at several popular voltages, with the line-conductor spacing and load power factor specified. Similar information can be obtained for other conductor materials, equivalent spacings of conductors, line voltages, and load power factors. The quantity plotted on the ordinate of the curves of Fig. 10—% voltage drop per kva-mile—is an important constant in primary-feeder design, which is used to a considerable extent throughout this paper.

Another measure of primary-feeder capability is the thermal-loading limit of the circuit conductors. This limit is usually interpreted in terms of the maximum current, in amperes, that a conductor can carry. This in turn limits the kva loading at a given voltage. This paper, however, deals exclusively with the analysis of primary-feeder circuits limited in their load-carrying capability by the % voltage drop.

Appendix II. Area Coverage by a Primary-Feeder Circuit

This analysis will illustrate, for a most simple and basic case, the technique employed throughout the following Appendixes in deriving equations which relate primary-feeder % voltage drop, load density, line impedance, and line loading.

Imagine a primary-feeder circuit emanating from some feed point, and ultimately reaching every distribution transformer in the area it serves. The circuit consists of a main feeder and laterals which are tapped off the main feeder, as shown in Fig. 11. For simplicity, the feeder area is shown as a square, with laterals uniformly spaced. Each lateral carries the same kva load, consisting of distribution transformers of the same size, equally loaded and uniformly spaced.

Along with this very simple, hypothetical single-feeder pattern in Fig. 11 is shown the model used in deriving an equation for the % voltage drop from the feed point at point a to the farthest distribution transformer at point c. For the purpose of writing an expression for the voltage drop from point a to intermediate point b, it is assumed in the model that the laterals do not exist and that the main feeder is uniformly loaded between a and b. When the voltage drop along the lateral bc is written, the model "forgets" about the individual distribution transformers, and treats the lateral as a uniformly loaded line serving a rectangular area $S/2$ long and 0.2 S wide.

In constructing the model of Fig. 11 it is assumed, then, that within area S^2 the load is uniformly distributed. Consequently a given fraction of the total area served by the feeder circuit will contain the same fraction of the total load. Area becomes equivalent to kva load, so that the product of area and distance becomes equivalent to the product of kva and miles. Since the % voltage drop is equal to the product of kva, miles, and some constant, the % drop from the feed point at a to the end of the last lateral at c is approximately

$$V_{ac}=V_{ab}+V_{bc} \tag{10}$$

$$V_{ab}=K_1\int_0^{0.9S}(Sdx)x=0.405K_1S^3 \tag{11}$$

$$V_{bc}=K_2\int_0^{S/2}(0.2S)(dy)y=0.025K_2S^3 \tag{12}$$

$$V_{ac}=0.405K_1S^3+0.025K_2S^3 \tag{13}$$

With distance S expressed in miles, constants K_1 and K_2 must have the units of kva/miles² in order for V_{ac} to have the units of kva-miles. Then in order for V_{ac} to have units of % voltage drop, constants K_1 and K_2 must also contain another constant which has the units of % voltage drop per kva-mile, so that

$$K_1S^3 \text{ or } K_2S^3 \equiv \left[\left(\frac{\text{kva}}{\text{miles}^2}\right)\times\left(\frac{\%\text{ voltage drop}}{\text{kva-mile}}\right)\right](\text{miles}^3) \equiv \%\text{ voltage drop} \tag{14}$$

The quantity kva/miles² is the load density in the uniformly loaded area S^2, and the % voltage drop per kva-mile factor in equation 14 is a constant which is deter-

mined by the electrical characteristics of the circuit itself.

The % voltage drop per kva-mile for the main feeder is known as K_M and for the lateral as K_L. Constants K_M and K_L can be obtained from Fig. 10, for copper-conductor lines with 37 inches equivalent spacing. Equation 13 can therefore be written

$$V_{ac}=0.405DK_MS^3+0.025DK_LS^3$$
$$=DS^3(0.405K_M+0.025K_L) \quad (15)$$

Although equation 15 is quite simple, and can be quickly evaluated for given values of D, S, K_M, and K_L, this equation applies only to the very special, hypothetical feeder pattern of Fig. 11. The importance of equation 15 is not in its application but rather in its illustration of the variation of primary-feeder % voltage drop with load density, total feeder loading or area served, and the constants which give the % voltage drop per kva-mile for the feeder circuit. Note that the constants K_M and K_L account for the effect on % voltage drop of all the following factors: line voltage; conductor material, size, and spacing; number of phases and wires making up the circuit; and load power factor.

Appendix III. The 4-Feeder Pattern

A 4-feeder pattern is one in which four primary circuits emanate from a distribution substation or feed point to serve the substation area or feed-point area. The purpose of singling out the 4-feeder pattern for special consideration is twofold: First, in comparing the relative load-carrying capabilities of different numbers of feeders emanating from a feed point, the 4-feeder pattern, because of its prevalance both in actual practice and in the recent literature, will be used as a reference for studying patterns employing different numbers of feeders. Second, the 4-feeder pattern will be studied intensively to show the effect on voltage drop of geometric variations in the arrangement of subfeeders and laterals.

Fig. 12 shows the 4-feeder pattern whose load-capability characterisitcs will serve as a reference for examining the relative capabilities of patterns containing a different number of feeders, or different geometric arrangement of mains, subfeeders, and laterals. Fig. 12 also shows the triangular-shaped area served by one of the four mains which radiate out from the feed point, and the model which is used to derive the % voltage drop from points a to c on the feeder circuit.

From the model of Fig. 12, the following approximate equation for % voltage drop may be written

$$V_{ac}=V_{ab}+V_{bc} \quad (16)$$

$$V_{ab}=K_MD\int_0^{0.9S}(x)(2xdx)=0.486K_MDS^3 \quad (17)$$

$$V_{bc}=K_LD\int_0^{0.9S}(y)(0.2Sdy)=0.081K_LDS^3 \quad (18)$$

$$V_{ac}=DS^3(0.486K_M+0.081K_L) \quad (19)$$

Equation 19 gives the % voltage drop in one of the primary-feeder circuits of the 4-feeder pattern pictured in Fig. 12, where D is the load density in kva per square mile, K_M and K_L are the % drop per kva-mile constants for the main and lateral respectively, and S is the length of the triangular-feeder area in miles. This equation exactly applies to only one very special hypothetical arrangement of four feeders emanating from a feed point, namely that of Fig. 12. Because of the apparently limited and presumably unrealistic situation for which equation 19 applies, it is important to examine the extent of applicability of equations like 19 to actual primary-feeder planning and design.

Variations of Primary-Feeder Geometric Patterns

There are literally an infinite number of different patterns that the four primary-feeder circuits emanating from a single feed point can assume. In general, such patterns will not only be geometrically irregular and unsymmetrical but also the load (in the form of distribution transformers) will never be uniformly distributed along the circuits. The analytical model of Fig. 12 is a case in which load increases at a constant rate along the main feeder. The total load carried by a lateral is directly proportional to its distance along the main feeder from the feed point.

At first glance, the particular four-feeder pattern of Fig. 12 would appear to be inefficient from the standpoint of achieving a reasonable voltage drop for the amount of load served. A more efficient pattern would appear to be one in which the major part of the load is located as near to the feed point as possible. But it must be borne in mind that in general any increase in load served also means a corresponding increase in area served. Consequently, in order for a large portion of the feeder load to be close to the feed point, a correspondingly large portion of the area served must be near to the feed point. But if each of the feeders emanating from a feed point are to be equally loaded, the areas they serve must be equal, assuming that load is uniformly distributed. Hence each feeder must serve its own sector of the area served from the feed point. However, there still remains a great deal of flexibility as to how this may be accomplished.

Fig. 13 shows eight different geometric variations out of the kaleidoscopic variety of possible 4-feeder patterns. Each main feeder radiating from the feed point serves an equal load contained in an equal area. Four triangular-shaped, or four diamond-shaped, contiguous feeder areas form a square that can be considered as the area served by a 4-feeder distribution substation; or the four main feeders can be considered to emanate from a feed point supplied by an express primary feeder carried from a remote distribution substation.

Table I which applies to Fig. 13 shows that, for these possible variations of a 4-

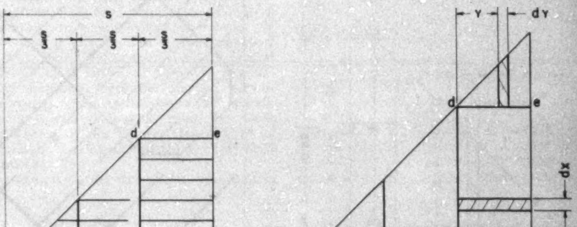

Fig. 14. Feeder-circuit arrangement and analytical model for pattern no. 3

feeder pattern, the relative % voltage drop for patterns no. 2 through 8 differs by no more than 10% from the reference % voltage drop for reference pattern no. 1, which is also the pattern of Fig. 12. The % voltage drop for each pattern was calculated in a manner similar to that resulting in equation 19 for pattern no. 1, with all load accounted for in every one of the feeder areas.

As a typical example of the voltage-drop evaluation for one of the patterns, consider pattern no. 3, shown with its analytical model in Fig. 14. The sum of the voltage drops in main, subfeeder, and lateral equals the total drop

$$V_{ae}=V_{ab}+V_{bc}+V_{cd}+V_{de} \qquad (20)$$

$$V_{ab}=DK_M\left[(S^2)\left(\frac{S}{3}\right)\right]=0.333DK_MS^3 \qquad (21)$$

$$V_{bc}=DK_M\left[2\left(\frac{S+2/3S}{2}\right)\left(\frac{1}{3}S\right)\right]\left(\frac{1}{3}S\right)=0.1852DK_MS^3 \qquad (22)$$

$$V_{cd}=DK_F\int_0^{0.678}\left(\frac{S}{3}\right)(x)dx=0.074DK_FS^3 \qquad (23)$$

$$V_{de}=DK_L\int_0^{0.388}y^2dy=0.0124DK_LS^3 \qquad (24)$$

Therefore

$$V_{ae}=DS^3(0.5182K_M+0.074K_F+0.0124K_L) \qquad (25)$$

The similarity between equation 25 for pattern no. 3 and equation 19 for pattern no. 1 is immediately apparent. The relative % voltage drops for these two patterns can be readily obtained by assigning values to K_M, K_F, and K_L. Fig. 10 can be used for this purpose in the following manner.

Assume that the main feeder for both patterns is no. 4/0 copper; the subfeeders of pattern no. 2 are no. 1/0 copper; and all laterals for both patterns are no. 4 copper. Assume all lines are 2,400/4,160 volts, 3 phases, 4 wires. Then from Fig. 10, $K_M=0.0031$, $K_F=0.005$, and $K_L=0.01$. Substituting into equations 19 and 25

$$\frac{V_{ae}\text{ in pattern no. 3}}{V_{ae}\text{ in pattern no. 1}}=\frac{0.0021DS^3}{0.00232DS^3}=0.906 \qquad (26)$$

The results obtained from computations similar to those which result in equation 26 are given in Table I.

It is possible, of course, to obtain extreme variations in relative % voltage drop for the eight feeder patterns of Fig. 13, or for any others that could be arbitrarily constructed, merely by assuming extreme nonuniformity of load distribution or other-conductor sizes for main feeders, subfeeders, and laterals. But it is interesting to note that the variety of subfeeder and lateral arrangements for these illustrative patterns is in effect equivalent to a similar variety of load-concentration patterns within the feeder areas.

Moreover, if in an actual system the main feeders carry approximately equal loads, and a reasonably small number of conductor sizes are standardized upon, then it is unlikely that subfeeder or lateral conductor sizes will differ very much, regardless of circuit arrangement, in areas of comparable load density. Equality of conductor size for different circuits in an actual system would be particularly true for the main feeder, in which most of the voltage drop is accounted for anyway, regardless of subfeeder and lateral arrangement.

Appendix IV. General Case of the n-Feeder Pattern

With the geometric and algebraic techniques employed in Appendixes II and III for the single-feeder and 4-feeder patterns serving as a background, a pattern of any number of feeders *n* emanating from a feed point will now be considered. Fig. 15 shows one feeder sector of an *n*-feeder pattern.

Note that for this general *n*-feeder case the last lateral on each main feeder is arbitrarily assumed to form the far boundary of the area served by that main feeder. This results in an area, or load served by the feeder circuit, that is somewhat smaller than would be served if the feeder load area were assumed to extend beyond the last lateral. Thus for a given % voltage drop, the assumed area ($S^2\tan\theta$) served by one of the *n* feeders is about 20% smaller than would be the case if the boundary of the feeder area were approximately 0.1 *S* farther away from the feed point than the last lateral, as was assumed for the single-feeder and 4-feeder patterns of Appendixes II and III. This new hypothetical picture of feeder area is adopted in order that the voltage-drop equations for this general *n*-feeder case yield somewhat conservative estimates for the capability of feeders, thereby allowing for extreme irregularities of load distribution and feeder-pattern geometry often encountered in actual systems.

The analytical model for the *n*-feeder pattern is also shown in Fig. 15. From this model

$$V_{ab}=K_MD\int_0^S x(2x\tan\theta)dx=0.667K_MDS^3\tan\theta \qquad (27)$$

$$V_{bc}=K_LD\int_0^{S\tan\theta}(0.2S)ydy=0.1K_LDS^3\tan^2\theta \qquad (28)$$

$$V_{ac}=V_{ab}+V_{bc}=DS^3(0.667K_M\tan\theta+0.1K_L\tan^2\theta) \qquad (29)$$

Let

$$0.667K_M=u,\text{ and }0.1K_L=v \qquad (30)$$

Then

$$V_{ac}=DS^3(u\tan\theta+v\tan^2\theta) \qquad (31)$$

where

$$\theta=\frac{360}{2n}\text{ degrees} \qquad (32)$$

Note that the area served by a single feeder can be found by dividing the feeder loading by the load density

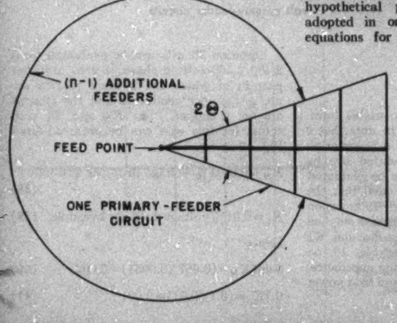
$$A_n=\frac{kva_n}{D}=S^2\tan\theta \qquad (33)$$

The total area served by all *n* feeders of the *n*-feeder pattern is then

$$A_{nt}=n\frac{kva_n}{D}=\frac{kva_{nt}}{D}=nS^2\tan\theta \qquad (34)$$

$$S=\left(\frac{kva_{nt}}{Dn\tan\theta}\right)^{1/2} \qquad (35)$$

It is now possible to write an expression for the total % voltage drop in one of the *n* feeders of an *n*-feeder pattern, in terms of the total loading of all *n* feeders, by substituting equation 35 into 31.



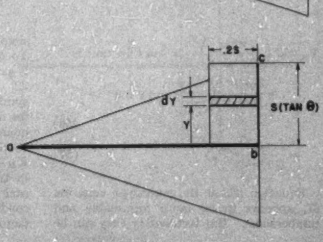


Fig. 15 (left and right). The general n-feeder pattern, with a single feeder sector and its analytical model

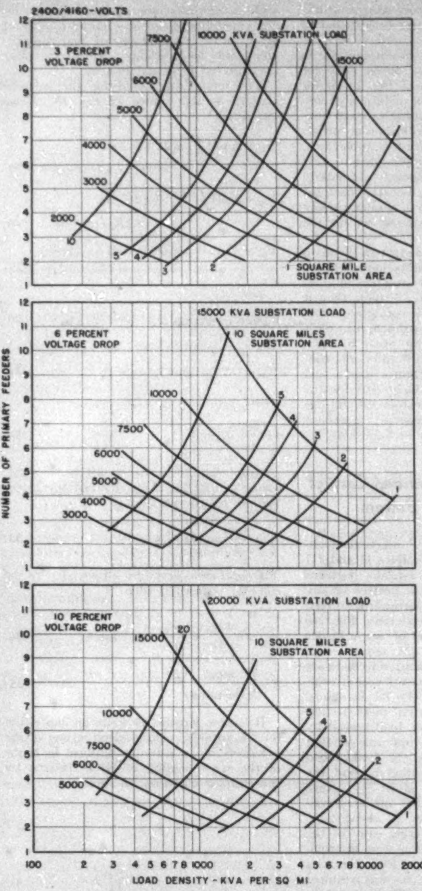

Fig. 16. Relationships between the system-planning parameters for systems employing 2,400/4,160-volt primary feeders. Number of primary feeders n versus load density D for 3, 6, and 10% feeder voltage drop V. Lines of constant substation or feed-point loading kva$_{nt}$ or constant substation or feed-point service area A$_{nt}$ are shown

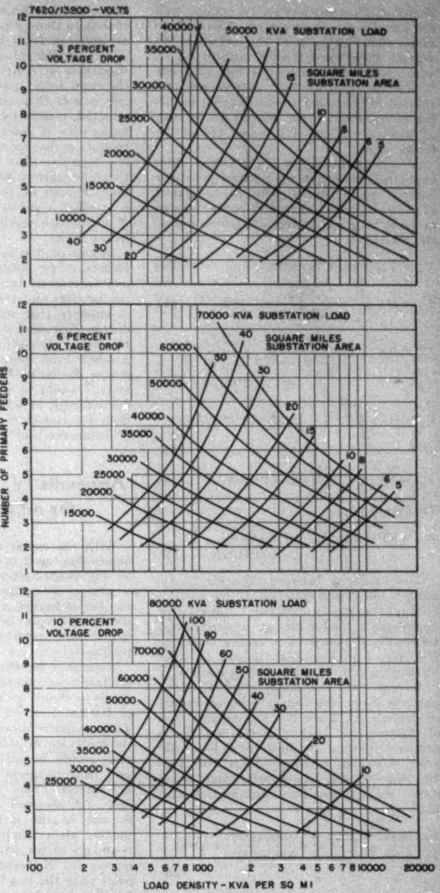

Fig. 17. Same as Fig. 16, except for systems employing 7,620/13,200-volt primary-feeder circuits

$$V_{ac}=D\left(\frac{kva_{nt}}{Dn\tan\theta}\right)^{3/2}(u\tan\theta+v\tan^2\theta)$$

$$=\frac{kva_{nt}^{3/2}}{D^{1/2}n^{3/2}}\left(\frac{u}{\tan^{1/2}\theta}+v\tan^{1/2}\theta\right) \qquad (36)$$

$$=\frac{kva_{nt}^{3/2}}{D^{1/2}n^{3/2}}(P_n) \qquad (37)$$

Equation 36, or its equivalent equation 37, appears to be quite formidable and cumbersome. But fortunately they can be simplified and put into more usable form. To do this, the first step is to note that θ is expressed as a function of n in equation 32. Hence the term represented by the symbol P_n in equation 37 can be evaluated for different values of n provided that the quantities u and v are given. In equation 30 the quantities u and v depend only on K_M and K_L. The constants K_M and K_L in turn depend, as shown in Fig. 10, on such factors as line voltage, line impedance, conductor material and size, and load power factor.

Equation 36 will now be evaluated for a 2,400/4,160-volt 3-phase 4-wire n-feeder pattern in which the n main feeders are no. 4/0 copper conductor and the laterals are no. 4 copper. The K_M and K_L constants for this case can be obtained from Fig. 10 and are

$K_M=0.0031\%$ voltage drop per kva-mile (38)

$K_L=0.01\%$ voltage drop per kva-mile (39)

Hence

$0.667K_M=(0.667)(0.0031)=0.0021$ (40)

$0.1K_L=(0.1)(0.01)=0.001$ (41)

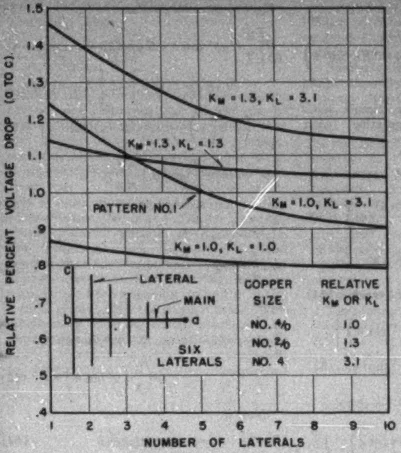

Fig. 18. Showing the effect of different combinations of main and lateral conductor sizes, and number of laterals, on % voltage drop, with pattern no. 1 as a reference

Then

$$P_n=\frac{0.0021}{\tan^{1/2}\theta}+0.001\tan^{1/2}\theta \qquad (42)$$

$$=\frac{0.0021}{\tan^{1/2}\dfrac{360}{2n}}+0.001\tan^{1/2}\frac{360}{2n} \qquad (43)$$

Now, if P_n as given in equation 43 is plotted versus n, the equation of the resulting straight line can be obtained by the "slope-intercept" method of analytic geometry. This equation is

$$P_n=(1.94n+23.1)10^{-4} \qquad (44)$$

Hence for one of the n feeders in a 2,400/4,160-volt n-feeder pattern utilizing no. 4/0 copper mains and no. 4 copper laterals

$$V_{ac}=\frac{kva_{nt}^{3/2}}{D^{1/2}n^{3/2}}(1.94n+23.1)10^{-4} \qquad (45)$$

Fig. 16 shows three sets of curves plotted from equation 45 for 2,400/4,160-volt primary-feeder circuits. The curves are a plot of n versus D for a wide range of values for kva_{nt}, which is the total loading of all n feeders comprising a pattern serving a substation or feed-point load area. Each set of curves is for a different % voltage drop. The curves for n versus D are drawn for both constant kva_{nt} or constant A_{nt}. The relationship between kva_{nt} and A_{nt} is given in equation 34.

It is interesting to note that equation 45 is not applicable to a 2-feeder pattern ($n=2$), for which $\theta=90$ degrees and $\tan\theta$ is infinite. For the evaluation of the 2-feeder pattern, two single-feeder patterns similar to the one discussed in Appendix II and pictured in Fig. 11 are combined to form a square-shaped area. The % voltage drop is then evaluated for different values of D and kva_{nt}, and the results are included in the curves of Fig. 16.

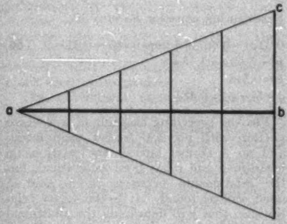
Since 7,620/13,200 volts is another popular primary-feeder voltage, Fig. 17 is a set of curves for n versus D, for different values of kva_{nt} and A_{nt} for 13.2-kv primary-feeder circuits.

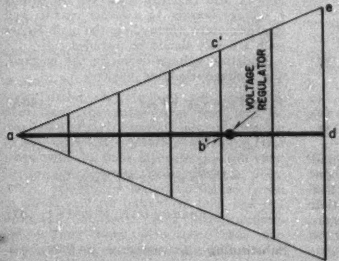
Sets of curves similar to those of Figs. 16 or 17 can be obtained for any line voltage, conductor material, or size by using the relationships and methods presented in the foregoing. To aid in making estimates of the effects of such changes, Fig. 18 can be used. The general n-feeder pattern of Fig. 15, which is used to obtain the curves of Figs. 16 and 17, utilizes five laterals for each of the n main feeders. Furthermore, the conductor sizes and material in Figs. 16 and 17 are no. 4/0 copper for the mains and no. 4 copper for the laterals.

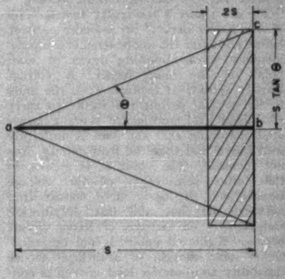
Fig. 18 shows the effect on % voltage drop of different main-feeder and lateral conductor-size combinations and different numbers of laterals. These curves are plotted with the conductor-size combination and number of laterals of Fig. 15 as a reference.

Appendix V. Effect of Supplementary Voltage Regulation on Primary-Feeder Capability

Supplementary voltage regulators or switched and unswitched capacitors are often used at various points along primary feeders to provide the equivalent of a voltage boost at their point of application. Such forms of supplementary voltage regulation are applied so as not to exceed the maximum







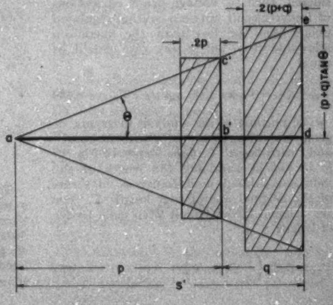


Fig. 19 (left and right). Primary feeders having equal voltage spread, with and without a supplementary voltage regulator employed in the main feeder, and the analytical model for the feeders

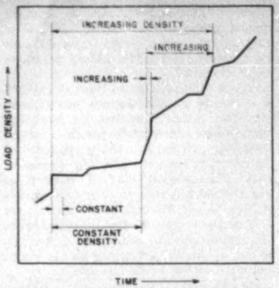

Fig. 20. Load density versus time. During certain relatively long periods the load density increases slowly, while during certain other relatively short periods the load density increases rapidly. The long-range trend, however, is one of increasing load density

allowable voltage spread on a section of primary-feeder circuit between voltage-regulated points, or between a voltage-regulated point and the end of the circuit. The following analysis will deal with the increase in primary-feeder capability provided by voltage-regulating equipment. Before proceeding with the analysis, which is based on voltage-drop considerations alone, it would be well to point out that it will be assumed throughout that thermal capability limits of feeder conductors are not reached when the addition of a voltage booster permits heavier circuit loading.

Fig. 19 shows a triangular feeder sector of one feeder area of an *n*-feeder pattern, before and after the application of a supplementary voltage-boosting device at some point on the main feeder. A voltage booster applied at a point b' on the main feeder ab will permit the feeder to carry additional load and hence serve a larger area, assuming that the load is uniformly distributed and that the load density does not increase. The point b' is chosen so that after installation of the voltage booster at b' the allowable % voltage drop between the first and last distribution transformers on sections of feeder circuit between regulated points is not exceeded. Or if some margin of additional feeder capability to allow for load growth is considered, then % voltage drops on sections of feeder circuit between voltage-regulated points may be less than the maximum allowable drop, but in any case should be equal

$$V_{ab}+V_{bc}=V_{ab'}+V_{b'c'}=V_{b'd}+V_{de} \qquad (46)$$

The purpose of the analysis diagrams, or geometric models of the "without-boost" and "with-boost" feeders, shown in Fig. 19 is to aid in obtaining the length of the voltage-regulated main-feeder S' in terms of the original main-feeder length S. For the original feeder circuit with main feeder of length S

$$V_{ab}=DK_M\left(\frac{2}{3}S^3\tan\theta\right) \qquad (47)$$

$$V_{bc}=DK_L(0.1S^3\tan^2\theta) \qquad (48)$$

$$V_{ab}+V_{bc}=DS^3\left(\frac{2}{3}K_M\tan\theta+0.1K_L\tan^2\theta\right) \qquad (49)$$

For the extended feeder circuit with supplementary voltage regulation, with main feeder of length $(p+q)=S'$

$$V_{ab'}=DK_M\left(\frac{2}{3}p^3\tan\theta\right)+DK_Mp\times\left(\frac{2(p+q)\tan\theta+2p(\tan\theta)}{2}(q)\right) \qquad (50)$$

$$=DK_M\left(\frac{2}{3}p^3\tan\theta\right)+DK_M\times[pq(2p+q)\tan\theta] \qquad (51)$$

$$V_{b'c'}=DK_L\left[(0.2p)(p\tan\theta)\left(\frac{p}{2}\tan\theta\right)\right]=DK_L(0.1p^3\tan^2\theta) \qquad (52)$$

$$V_{ab'}+V_{b'c'}=D\left(\frac{2}{3}K_Mp^3\tan\theta+K_Mpq\times(2p+q)\tan\theta+0.1K_Lp^3\tan^2\theta\right) \qquad (53)$$

Note that the last lateral on a main-feeder section is assumed to serve a rectangular area (2 $S\tan\theta$) long and (0.2 S) wide. Such an area is somewhat larger than the trapezoidal area which would have to be served in order not to infringe on the area served by a contiguous feeder in such a pattern. This assumption introduces negligible effect on the results of the analysis.

To write $V_{b'd}$ a slightly different approach will be taken. This drop will be written as the summation of the products of all the load lying beyond some point x on the main and the distance of that point x from b'

$$V_{b'c}=DK_M\int_p^{p+q}(S'^2\tan\theta-x^2\tan\theta)dx$$

$$=DK_M\tan\theta\left(S'^2(p+q)-\frac{(p+q)^3}{3}-S'^2p+\frac{p^3}{3}\right)=DK_M\tan\theta\times\left(S'^2q-p^2q=pq^2-\frac{q^3}{3}\right) \qquad (54)$$

Now $S'=(p+q)$, so that

$$V_{b'd}=DK_Mq^2\tan\theta\left(p+\frac{2}{3}q\right) \qquad (55)$$

$$V_{de}=DK_L\left(0.2(p+q)\frac{(p+q)^2\tan^2\theta}{2}\right)=DK_L[0.1(p+q)^3\tan^2\theta] \qquad (56)$$

$$V_{b'd}+V_{de}=DK_Mq^2\tan\theta\left(p+\frac{2}{3}q\right)+0.1DK_L(p+q)^3\tan^2\theta \qquad (57)$$

To find the relationship between p and q to satisfy the assumed equality of the % voltage drop between the first and last distribution transformers in each section of primary feeder between voltage-regulated points, equations 53 and 57 may be equated

$$V_{ab'}+V_{b'c'}=V_{b'd}+V_{de} \qquad (58)$$

$$D\left[\frac{2}{3}K_Mp^3\tan\theta+K_Mpq(2p+q)\tan\theta+0.1K_Lp^3\tan^2\theta\right]=L\left[K_Mq^2(\tan\theta)\times\left(p+\frac{2}{3}q\right)+0.1K_L(p+q)^3\tan^2\theta\right] \qquad (59)$$

$$\frac{2}{3}p^3+2p^2q-\frac{2}{3}q^3=0.1\frac{K_L}{K_M}\times\tan\theta(3p^2q+3pq^2+q^3) \qquad (60)$$

Let

$$0.1\frac{K_L}{K_M}=w \qquad (61)$$

then

$$\frac{2}{3}p^3+p^2q(2-3w\tan\theta)-pq^2(3w\tan\theta)-q^3\left(\frac{2}{3}+w\tan\theta\right)=0 \qquad (62)$$

Now if

$$S'=(p+q)=1\text{, then }q=1-p \qquad (63)$$

Substituting $q=(1-p)$ into equation 62 and simplifying

$$p^3\left(w\tan\theta-\frac{2}{3}\right)+2p-\frac{2}{3}=w\tan\theta \qquad (64)$$

Equation 64 will now be solved for $\theta=45$ degrees or $\tan\theta=1$, which is the 4-feeder pattern. To obtain a numerical value for w, consider a no. 4/0 copper main feeder and no. 4 copper laterals, so that $K_L/K_M=3.1$. Note that for given conductor sizes in main and laterals, and with 3-phase circuits of the same conductor spacing assumed, K_L/K_M is independent of primary-feeder voltage. Then

$$W=0.1(3.1)=0.31 \qquad (65)$$

Substituting equation 65 into 64

$$0.31p^3-0.667p^3+2p-0.667-0.31=0 \qquad (66)$$

$$p^3-5.63p+2.75=0$$

$$p=0.513$$

$$q=(1-p)=0.487$$

For the preceding example of a 4-feeder pattern with no. 4/0 copper main feeder and no. 4 copper laterals the relationship between p and q has been established, but the relationship between $(p+q)$ and S must still be found. It is this latter relationship that will determine the additional area or load that can be served by adding a voltage booster to a feeder circuit, and approximately where along the main feeder such a device should be installed.

Equating voltage drops on the original, and voltage-regulated feeders

$$V_{ab}+V_{bc}=V_{ab'}+V_{b'c'} \qquad (46A)$$

$$DS^3\left(\frac{2}{3}K_M\tan\theta+0.1K_L\tan^2\theta\right)=D\left[\frac{2}{3}K_Mp^3\tan\theta+K_Mpq(2p+q)\tan\theta+0.1K_Lp^3\tan^2\theta\right] \qquad (67)$$

Substituting the values of $p=0.513$, $q=$

0.487, and $K_L/K_M=3.1$ into equation 67, $S=0.805$. Then

$$\frac{(p+q)^2}{S^2}=\frac{1}{0.65}=1.54 \qquad (68)$$

Thus by adding a voltage booster on a feeder circuit, and allowing the circuit to be extended to pick up additional load so that the voltage drop in the two voltage-regulated sections of the circuit is the same, approximately 54% additional load can be served.

It is interesting to note that if a voltage booster is installed in the main feeder of the simple 1-feeder pattern of Appendix II, the additional area of uniform load density that can be served, such that the voltage drop from feed point to regulator equals that from regulator to end of main, is 59% greater than the original area. This relationship can be easily visualized by noting that % voltage drop is proportional to S^3. Hence if the voltage drop is allowed to double, then for the new, lengthened circuit, S becomes $2^{1/3}$ times the original value of S, and the area served by the extended circuit is $(2^{1/3})^2=1.59$ times the original area.

Similarly, if two voltage boosters permit approximately three times the original voltage drop from feed point to the last distribution transformer on the circuit, then the extended area that can be served by the feeder with two boosters is approximately $(3)^{2/3}=2.08$ times the original area served by a feeder with no voltage boosters. Thus for a primary-feeder circuit serving an area of reasonably uniform load density, the amount of load the feeder can serve varies as the two-thirds power of the number of voltage boosters plus one, applied on that feeder, provided that the current-carrying capacity of the feeder is not exceeded.

Variation in both the number of primary-feeder sectors comprising a feeder pattern and the arrangement of subfeeders and laterals has surprisingly little effect on the relative additional area at uniform load density that can be served by adding one or more supplementary voltage regulators to an existing feeder. This relative additional area can be estimated from the two-thirds power relationship just given, and is therefore about 60% greater than the original area for one regulator, and 100% greater than the original area for two regulators, provided that thermal capability limits of circuits are not exceeded.

Discussion

B. M. Jones and **C. N. Clark** (Duquesne Light Company, Pittsburgh, Pa.): Some general comments on the planning practices of our company are offered in connection with this general subject; they do not bear directly on the technical contents of this useful and informative paper but we feel they might be interesting. Our comments concern the constant substation-size plan and the constant substation-area plan.

EXISTING SUBSTATIONS, 4 KV

Where the ultimate size of an existing substation has already been reached, our practice has been to gradually reduce the area served and provide additional capacity elsewhere, either by expanding near-by substations or installing additional substations and circuits. Similarly, for substations which have not reached their ultimate size, we just keep on providing capacity where economical until they do reach their ultimate size.

The economical factors considered in utilizing the existing substation sites to their full economical advantage are: land and buildings—utilizing to full advantage, or expanding at that site to the economical limit; available communication facilities; off street parking—proper evaluation of losses and taking cognizance thereof; storage of small repair parts; and toilet facilities. Also, for existing substations, zoning permits or municipal installation permits are much easier to obtain in many cases than for new sites.

These paragraphs referring to substations having reached their ultimate size come under the constant substation-size plan, and the substations that will be expanded to their ultimate size are initially in the constant substation-area plan, but when reaching their ultimate size will then be in the constant substation-size plan. These substations include attended, none of which we have built since 1925, and unattended automatic and semiautomatic substations, many with more than one circuit and one transformer bank.

NEW SUBSTATIONS, 4 KV

Beginning in 1947, all new 4-kv distribution substations have been of the package type, and their capacity has been used to provide relief for the existing substations by a gradual reduction in the area being supplied by the then existing substations. This practice results in the constant substation-size plan in most cases, but in some cases it is economical to expand the existing substations up to the ultimate before changing to the constant substation-size plan. Incidentally, some of this additional capacity in the existing substations is needed in attended and built-up types and in package types of installations, the latter by installing another unit in addition to the original one or by replacing the original one with a larger one.

Where successive package units are installed on one substation site, this approaches the constant substation-area plan until such time as the maximum number of units has been installed on that site, after which the area is again reduced by shifting load to other new or existing substations.

SUBSTATION SITE DIFFICULTIES, 4 KV AND OTHERS

This is an everlasting problem, and it is becoming worse as the movement to rural areas continues at an accelerated pace. Zoning requirements, public acceptance, and many other factors sometimes force the utility to depart from the perfect economical solution in some cases by installing more 4-kv substation capacity—unit types or other types—on one site. Our company has encountered instances where it could not get the site in the vicinity of the most economical location, and hence was forced to choose other alternatives.

Charles Morrison and **C. C. Wolf** (The Potomac Edison Company, Hagerstown, Md.): As is frequently the case, the use of a hypothetical and generalized method reveals certain fundamental relationships which might have been hidden in a specific approach to the solution of practical problems. The authors have not only provided the planner with some sound relationships but they have recognized certain practical aspects of planning which are sometimes overlooked. One of these is the recognition of increasing load density as distinct from increased load density.

While our own problems of distribution-substation planning are not related to load density in the usual terms of kva per square mile, we believe the authors are to be commended on their excellent treatment of the subject in the manner which is appropriate when considering urban and suburban areas. We like their inclusion of the kva-mile concept in Appendix I. During the past year we have developed what we call a linear approach to the problem of distribution-substation or feed-point planning in which kva-miles is the significant parameter. For rural distribution systems this seems to us to be the more suitable approach.

From our work we have determined that the % voltage drop per kva-mile, referring to Fig. 10, for 12.47-kv feeders is $(r\cos\theta+X\sin\theta)/1{,}555$, in which the term $(r\cos\theta+\sin\theta)$ would have the following values, based on a conductor temperature of 75 degrees centigrade, an equivalent conductor spacing of 5 feet, and a load power factor of 0.9:

No. 6 copper, 2.554
No. 2 copper, 1.202
No. 2/0 copper, 0.749
No. 4/0 copper, 0.577

Using these values we would obtain the following % voltage drop per kva-mile for 12.47-kv 3-phase feeders:

No. 6 copper, 0.00164
No. 2 copper, 0.00077
No. 2/0 copper, 0.00048
No. 4/0 copper, 0.00037

These figures agree substantially with the corresponding values taken from the curves of Fig. 10.

In Appendix V the effect of supplementary voltage regulation on primary-feeder capability is very well presented.

While again our own approach to this aspect of planning has been on a linear basis, we recognize both the need and the value of the relationships developed in the authors' presentation. It is of interest to note that on a linear basis the addition of a voltage regulator and the extension of a feeder to pick up additional load would permit a uniformly loaded line to be lengthened by about 41%, whereas the authors find that 59% additional area of uniform density can be supplied by the addition of a regulator under similar limits of voltage spread. This is not a discrepancy, but it does demonstrate the reason for our approach to the problems of primary-feeder capability where load-area geometry approaches a single dimension as it frequently does in rural distribution systems.

J. R. Oberholtzer (Commonwealth Associates, Inc., Jackson, Mich.): This paper presents a rather complete analysis of the relation between the various parameters which affect the layout of a primary distribution system. It is useful to remember these relations when analyzing specific systems so that the anticipated results of proposed changes can be estimated without excessive detailed calculations. Furthermore, the recognition of these ideal relations should prevent the system planner from drawing improper conclusions of long-range effects of system changes from a limited study of proposed immediate programs.

The relative voltage drops given in Table I, for various primary line patterns, are very nearly equal. Thus it appears that any reasonably efficient arrangement of lines will result in about the same primary voltage drop. It is noted that this analysis assumed that all lines, including the laterals, would be 3 phase. The differences between voltage drops for the various patterns might be expected to increase if the laterals were single phase, which may be closer to typical system conditions.

It would be helpful if a similar analysis could be made of the relative weight of copper required for the various patterns. This would be a good measure of the relative costs. With the patterns as they are drawn in Fig. 13 there would probably be wide variations. However, if the lateral spacing were maintained approximately equal among the patterns, which would be the case if the same distribution transformer locations were assumed, it is believed that the weight of copper would be very nearly the same.

Benefits which may be obtained by the use of supplementary regulators are outlined in the paper. The effective use of these regulators will result in heavier ampere loading of feeder conductors which will result in a rapid increase in power losses in these feeders. This should be considered in the comparison of this with other methods of increasing feeder areas.

F. C. Van Wormer (General Electric Company, Schenectady, N. Y.): In Appendixes II and III the derivations for % voltage drop in the feeder are based on only five laterals with laterals spaced $0.20S$ apart. The paper would have been of more general use and more realistic if the authors allowed any number of laterals spaced a fixed distance apart, such as a representative city block spacing.

The expression for V_{ab} in equation 11 is incorrect. It should be

$$V_{ab}=K_1\int_0^{0.9S} S(S-x)dx=0.495K_1S^3 \quad (11)$$

The expression for V_{ab} in equation 17 is also incorrect. It should be

$$V_{ab}=K_MD\int_0^{0.9S}(S-x)(S+x)dx$$
$$=0.657K_MDS^3 \quad (17)$$

The expression for V_{cd} in equation 23 is not complete since it omits the voltage drop in lateral *cd* due to the load picked up on the last branch *de* as shown in the right-hand side of Fig. 14. Consequently equation 25 is not complete and the results in equation 26 will also be affected.

The expression for V_{bc} in equation 28 is too large. The feeder area covered by the last lateral *bc* is indicated in the lower right-hand side of Fig. 15 as a rectangle instead of the trapezoidal area in the left-hand side of Fig. 15. The trapezoid area is 10% less than the rectangle. Thus equation 28 should be

$$V_{bc}=0.09K_LS^3\tan^2\theta \quad (28)$$

The authors consider feeder areas where the length of lateral is proportional to the length of the main and, in addition, the load per lateral is also proportional to the length of the main. This last factor results from the use of only five laterals, making the width of area per lateral $=0.20S$. This type of pattern is not encountered very frequently but it does simplify the mathematics. Based on these assumptions

$$V_{ac}=V_{ab}+V_{bc}=K_1\frac{DS^3}{kv^2}+K_2\frac{DS^3}{kv^2}$$
$$=\frac{DS^3}{kv^2}(K_1+K_2)$$

Thus

$$V\propto\frac{DS^3}{kv^2} \quad (69)$$

From this

$$S\propto\frac{V^{1/3}kv^{2/3}}{D^{1/3}}$$

$$\text{Feeder area } A\propto S^2\propto\frac{V^{2/3}kv^{4/3}}{D^{2/3}}$$

$$\text{Feeder kva}\propto AD\propto V^{2/3}kv^{4/3}D^{1/3}$$

or for n feeders

$$kva_{nt}\propto V^{2/3}kv^{4/3}D^{1/3}n \quad (70)$$

Equations 1 through 9 of the paper follow from these relations.

The relation $n\propto 1/kv^2$ given in equation 1 applies to a concentrated load at the end of a fixed length of line. For area coverage this relation becomes $n\propto 1/kv^{4/3}$ as seen from equation 70. The relation given in equation 3 also follows from equation 70.

In accordance with equation 3, if the feeder voltage is multiplied by $\sqrt{3}$ and the number of feeders is reduced from eight to six, kva_{nt} can be increased by 56% instead of 33% as stated below equation 3. When the feeder voltage is tripled and the number of feeders reduced from eight to four, the substation size may be increased 2.17 times.

Equation 7 should be $n\propto 1/D^{1/3}$ as seen from equation 70. Equation 9 follows from equation 69 when length S is held constant.

W. J. Denton and D. N. Reps: The remarks of Mr. Jones and Mr. Clark are very pertinent to some of the practical aspects of distribution-substation planning. The continual shifting from constant substation-area to constant substation-size plans is a frequently encountered situation in many systems. In our paper we pointed out that between these two extremes in planning philosophy there are an infinite variety of intermediate types of action which may call for both the addition of more capacity at an existing substation site and the location of more capacity at new sites. The nice feature of the picture presented by Fig. 16—for the primary-feeder voltage of 4 kv applicable to the Duquesne Light Company's situation—is that system-growth lines of either constant substation-size or constant substation-area are shown. Interpolation between these lines, moving in the direction of increasing load density, permits the planner to estimate what may have to be done to primary-feeder circuits when substation additions are made. Two parameters which can be determined from these curves are the change in the number of primary feeders required and the % voltage drop in primary feeders as load grows and distribution-substation capacity is added to the system.

As Mr. Morrison and Mr. Wolf state, the difference between considering increased, or increasing, load density is an important one. The first implies that corrective measures may comprise the only planning procedure, whereas the second indicates that preventive planning could be the goal of the distribution engineer. Corrective measures are usually a piecemeal process, and do not ordinarily result in long-range economy. The figure of 41% additional allowable line length for a uniformly loaded line after the addition of a supplementary voltage regulator is obtained in a very straightforward manner. Total % voltage drop on the line is proportional to the product of kva load and miles length. Lengthening the line by 41% will result in 141% of both the original kva loading and the miles length, and hence twice the original drop. The regulator permits a voltage spread equal to the original spread.

For the line serving load uniformly distributed in a given area, the addition of a voltage booster permits the line to be lengthened 26%. It will be noted that $(1.26)^2$ gives 1.59 times the original area, assuming that the geometric shape (say, rectangular) of the enlarged area remains similar to that of the original area.

With regard to the study of different geometric patterns for primary-feeder circuits, Mr. Oberholtzer indicates that single-phase rather than 3-phase laterals might show greater deviation in the relative % drop than the approximately ±10% obtained for the patterns shown in Fig. 13. It is difficult to find an exact sort of approach to a point such as this, because, even in Fig. 13, minor adjustments in subfeeder conductor sizes were made in order to keep % voltage drop for each pattern within the 10% limits. Presumably, then, further adjustments in subfeeder sizes could be made so that, even if single-phase laterals are considered, patterns of equal drop could still be devised. We too believe that Mr. Oberholtzer is correct when he says that the weight of conductor would not be affected to any great extent, regardless of feeder pattern, so long as the same set of distribution transformers are to be served, with reasonably equal % voltage drop for each pattern considered.

In general, the investment in overhead primary-feeder circuits, in dollars per kva load served, varies very little with either circuit capability or even circuit voltage. Most laterals are the same, standardized (and often minimum allowable) size regardless of the capability of the main and subfeeders. Since laterals form by far the largest portion of primary circuit mileage, variation in mains capability affects total circuit cost only slightly, and from the standpoint of total system cost, even less.

Mr. Oberholtzer's recognition of the increased % power loss with the use of supplementary voltage regulators is an important point. General studies we have made indicate that the % loss in primary-feeder circuits is directly related to the % voltage drop, e.g., the doubling of total drop by the addition of a regulator will approximately double the % power loss in that circuit. The inclusion of power, and energy, losses in economic studies is highly desirable. However, in planning new systems or future systems, good planning and design from the standpoint of providing good voltage for customers will virtually assure economy in losses. Moreover, there should not be a significant difference in losses in alternative system plans calling for equal service quality. However, in existing systems where voltages are too low and drops are excessive, high energy losses and poor economy are usually accompanying effects.

The first point Mr. Van Wormer raises is the use of five laterals, spaced 0.2*S* apart (*S* being total feeder length) in our derivations of Appendixes II and III. Actually the choice of number of load take-off points has no bearing on the problem, inasmuch as for the purpose of computing the total drop in the main, uniformly distributed loading was assumed. The only effect that laterals have on total voltage drop, with such an approach, is the loading of the farthermost lateral, which, we assumed, served an area of width 0.2 times the total length of the main feeder. For simplicity's sake, however, the "number of laterals" concept was used to differentiate between various possible load burdens placed on the last lateral in such a configuration. In any event, Fig. 18 shows how relative voltage drop is affected by changes in the number of laterals or conductor sizes used for main and lateral. The reference value of 1.0 for pattern no. 1 is indicated on this figure, thus permitting rapid estimation of the relative drop for patterns using other numbers of laterals and conductor sizes.

In equation 11 the expression for V_{ab} is not incorrect; it is approximate, as stated in the sentence immediately preceding this expression. Admittedly, however, Mr. Van Wormer's equation gives a closer approximation of the total % voltage drop incurred in a feeder circuit with discrete load take-off points, but with assumed continuous loading for the purposes of analysis. But equation 11 and also equation 17 are not intended for further application in computations, and hence this rougher approximation of ours is not carried into the work from which results such as Figs. 16 and 17 are obtained. Given the choice now, however, we would be more than happy to use the integral expression Mr. Van Wormer suggests. Our results comparing relative capabilities of different types of circuit patterns, voltages, and conductor sizes would not be affected to any great extent using either integral.

The expression for V_{cd} in equation 23 is indeed not complete, omitting the voltage drop in lateral *cd* due to the load picked up on the last branch *de*. Thus equation 23 should be

$$V_{cd}=0.074DK_FS^3+DK_F\left(\frac{1}{2}\right)\left(\frac{S}{3}\right)^2\left(\frac{2S}{3}\right)$$

where the second term is the missing part. Hence

$$V_{cd}=0.074DK_FS^3+0.037DK_FS^3 \qquad (23)$$

and equation 25 becomes

$$V_{ae}=DS^3(0.5182K_M+0.11K_F+0.0124K_L) \qquad (25)$$

and equation 26 becomes

$$\frac{V_{ae}\text{ in pattern no. 3}}{V_{ae}\text{ in pattern no. 1}}=\frac{0.0024}{0.00232}=1.03 \qquad (26)$$

Thus the effect of this omission is quite small, and, as a matter of fact, results in an even closer equality between the voltage drops of pattern nos. 1 and 4. There is, of course, some flexibility in the way voltage drops for the patterns of Fig. 13 can be obtained by methods of integration, since circuit configuration in "fringes" and "corners" is not intended to be exactly stipulated. This same sort of effect enters into the slight discrepancies that would be obtained from alternately considering that the last lateral serves a trapezoidal or rectangular area. Assumption of a rectangular area gives somewhat less optimistic results for feeder capability, and consequently for this reason we made the latter assumption in writing equation 28.

Relationships involving variation in the number of primary feeders emanating from a feed point become very difficult to derive, express, and manipulate. This paper represents, to our knowledge, the first attempt to approach the problem of overhead distribution-circuit general analysis with the inclusion of the number of feeders as an independent variable. The difficulty can be observed in equation 45, which shows that the number of feeders enters a general expression relating the planning parameters in the manner given by the factor $(1.94n+23.1)$ for the case illustrated for 2,400/4,160-volt circuits utilizing no. 4/0 copper mains and no. 4 copper laterals. More generally, however, the factor P_n in equation 37 houses the effect of n on all the other parameters. Realizing that few distribution engineers can devote the time required to manipulate equation 37 to suit their individual systems and plans, we computed the curves of Figs. 16 and 17 from equation 37. The distribution engineer primarily interested in what an approach such as ours can do to help him solve his problems may begin directly with Fig. 16 or 17, or from a similar figure for another primary voltage, and estimate the changes that must be made in distribution-substation size and location, number of primary feeders, or improvements in service quality, to follow a desired plan of system growth.

Equations 1 through 9 were gleaned from the general equation 37, and were easy to write only for the cases where the number of primary feeders remained constant, such as in equations 2, 4, 6, and 9. In equations 1, 3, 5, 7, and 8, where n could be an independent variable, these equations were only approximate. To find the full effect of system changes on n, Figs. 16 and 17, or similar information, should be employed.

D-C Machines: Response to Impact Excitation

J. J. BROCKMAN
NONMEMBER AIEE

C. E. LINKOUS
ASSOCIATE MEMBER AIEE

WHEN calculating the transient performance of a d-c system it is essential to know how the d-c machines in the system respond to changes in excitation voltage. Conventional d-c motors and generators have rolled steel magnet frames. Such frames have excellent mechanical strength, which adds to the serviceability of the machines, and they provide low reluctance paths for the main-pole and commutating-pole fluxes. However, they also afford comparatively low resistance paths for the eddy currents which tend to oppose any flux changes.

This paper presents a method of calculating the rise of main-pole flux and exciting current, when a step function of voltage is applied to the shunt field of a d-c machine with a solid magnet frame. The method may be extended to calculate the rise of commutating-pole flux during an increase in armature current.

Equations for flux and exciting-coil current have been developed by Dunaevskii,[1] who considers a magnetic circuit consisting of a solid section, a laminated section, and an air-gap in series combination. In his analysis he substitutes an equivalent rhombic cross-section for a rectangular one.

In the present paper, Dunaevskii's equations are applied to find the build-up of main-pole flux and exciting current when the field circuit is subjected to an abrupt change in voltage. A number of simplifying assumptions are made as follows:

1. The solid, rectangular cross-section frame may be replaced by one of rhombic section; see Fig. 1.

2. The exciting coil is wound on the solid section. Then the field due to current in the coil penetrates the solid section from all sides.

3. The length of the solid frame section, associated with a shunt field coil, is one-half the main-pole pitch, measured on the mean frame diameter; see Fig. 2.

4. The flux distribution in the laminated sections of the magnetic circuit and in the air gap is the same as the flux distribution in the solid section.

5. The static saturation curve represents the relation between frame flux and magnetic-circuit permeance under transient conditions.

6. The leakage coefficient k_l is not appreciably affected by eddy currents in the solid section or by magnetic-circuit saturation.

7. The saturation curve of the d-c machine may be approximated by several straight lines.

8. The field flux and exciting current, as functions of time, are calculated from several flux and current equations. One flux equation and one current equation are written for each straight-line portion of the saturation curve. The final flux and current expressed by one set of equations define the initial conditions for the equations that follow. However, no attempt is made to match the eddy currents. At the instant a new set of equations for flux and current becomes effective, the eddy currents are assumed to be zero.

Assumptions 1, 4, and 6 are similar to those made in reference 1. Excitation tests on two experimental choke coils with solid yokes, one rectangular and the other rhombic in cross section, produced almost identical results (see reference 1).

The equations for flux and exciting current are derived on the basis of assumption 2, i.e., the exciting coil is around the solid iron section so the field enters the iron uniformly on all sides. This is not the arrangement in a d-c machine. The field around the frame, due to increasing main-pole exciting coil current, has a rather complicated pattern. The field strength is highest on the inside radius of the frame, so that the flux enters along this surface more rapidly than it does on the outside frame surface, or the end surfaces.

When saturation effects are considered, assumptions 7 and 8 greatly simplify the calculations. However, these assumptions result in discontinuities in slopes of the calculated flux and current curves.

Nomenclature

All linear dimensions are in inches.

a = width of rhombic section, see Fig. 1
a' = width of rectangular magnet frame
b = height of rhombic section, see Fig. 1
b' = height of rectangular magnet frame section
i = instantaneous shunt field current, amperes
i_0 = shunt field current at time zero, amperes
Δ_i = change in field current between time zero and time infinity, amperes
k_l = main field flux leakage coefficient equal to the ratio of total field-flux linkage to field-flux linkage due to flux that enters the armature
l_m = half a pole pitch measured on the mean diameter of the magnet frame, see Fig. 2
N = turns per pole
P = number of poles
R = field circuit resistance per pole, ohms
t = time, seconds
T_0 = field time constant due to flux that enters the armature, seconds
T_β = frame time constant, seconds
ρ = electrical resistivity, ohm-inches
ϕ = instantaneous main-field frame flux, megalines
ϕ_0 = main-field frame flux at time zero, megalines
$\phi_1-\phi_2$ = change in field flux, megalines, corresponding to a change in field current, i_1-i_2, along a straight-line portion of the static saturation curve
$\Delta\phi$ = change in main-field flux between time zero and time infinity, megalines

Comparison of Test and Calculated Results

The main-field voltage of a 165-kw exciter was suddenly increased from 0.1 to 2.5 times normal. For test purposes,

Paper 55-109, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing November 24, 1954.

J. J. BROCKMAN is with the General Electric Company, Schenectady, N. Y., and C. E. LINKOUS is with the General Electric Company, Fort Wayne, Ind.

The authors wish to thank H. D. Snively and E. P. Smith for their very helpful suggestions in the preparation of this paper.

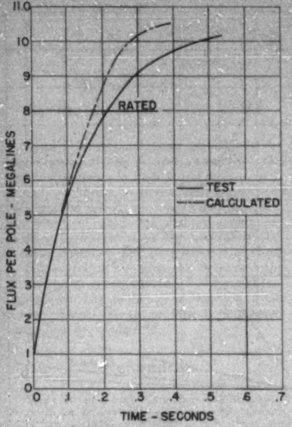

Fig. 3. Voltage build-up of 165-kw, 250-volt exciter

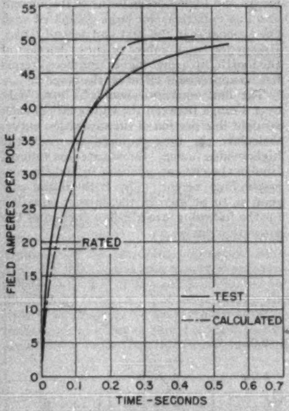

Fig. 4. Field current during voltage build-up of 165-kw, 250-volt exciter

the pole windings were connected in parallel, with an added series resistor to limit the field current to 2.5 times rated field current. Under these conditions the average rate of flux build-up for the first 0.2 second was 4.2 per unit per second. This exceptionally high rate of rise of flux permits comparison of test and calculated results under the most severe conditions. Test and calculated field flux and current curves are shown in Figs. 3 and 4.

Three 1,750-kw, 600-volt generators were identically designed except for magnet frame construction. To compare performance, one machine has a conventional solid steel frame, and the other two are laminated. Figs. 5 and 6 are plots of main-field flux and current for the rolled-steel-frame generator after the application of 1.67 times normal field voltage.

These comparisons indicate the method of calculation, including the effect of eddy currents, yields reasonably accurate predictions of the build-up of main-field flux and current. While some of the assumptions, accepted to simplify the analysis, are difficult to justify, they appear not seriously to affect the accuracy of the results.

Appendix I. Calculation of Shunt Field Flux and Current

Fig. 2 shows a portion of the main-pole magnetic circuit associated with a shunt field coil of a d-c machine. The flux path consists of a length through the solid magnet frame approximated by l_m, the laminated sections of the main-pole core and rotor, and the air gap.

For analysis, the magnetic circuit of Fig. 2 is replaced by the simplified circuit shown in Fig. 7. The length of path in the solid section l_m is the same as that in Fig. 2. The simplified circuit has a uniform rhombic cross section. The area of the rhombus is equal to the cross-sectional area of the solid frame. Its dimensions are related to those of the rectangular frame, Fig. 1, as

$$a=\sqrt{2}a'$$

$$b=\sqrt{2}b'$$

A step function of voltage is applied to the exciting winding at time zero. Prior to switching, the exciting current is assumed constant and the eddy currents are zero.

The equations for flux and exciting current, derived by Dunaevskii are

$$\phi=\phi_0+\Delta\phi\left[1-\sum_{\nu=1}^{\infty}\phi_\nu e^{-\alpha_\nu\frac{t}{k_lT_0}}\right] \quad (1)$$

$$i=i_0+\Delta i\left[1-\sum_{\nu=1}^{\infty}i_\nu e^{-\alpha_\nu\frac{t}{k_lT_0}}\right] \quad (2)$$

In these equations ϕ_ν and i_ν are given by

$$\phi_\nu=\left(\frac{T_\beta}{T_0}\right)^2\times \frac{1-\dfrac{q_\nu^2(k_l-1)}{T_\beta/T_0}}{q_\nu^3\left[(k_l-1)q_\nu+\dfrac{q_\nu-(1-\cos q_\nu)\sin q_\nu}{\cos^2 q_\nu}\right]} \quad (3)$$

$$i_\nu=\left(\frac{T_\beta}{T_0}\right)\times \frac{1}{q_\nu\left[(k_l-1)q_\nu+\dfrac{q_\nu-(1-\cos q_\nu)\sin q_\nu}{\cos^2 q_\nu}\right]} \quad (4)$$

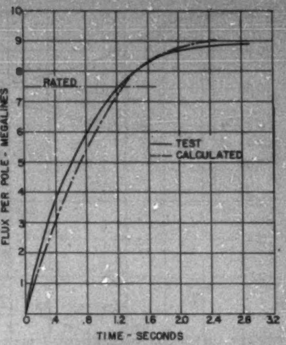

Fig. 5. Voltage build-up of 1,750-kw, 600-volt generator

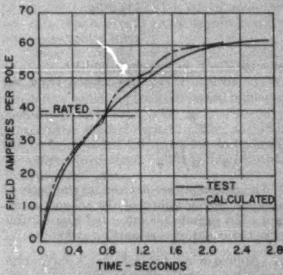

Fig. 6. Field current during voltage build-up of 1,750-kw, 600-volt generator

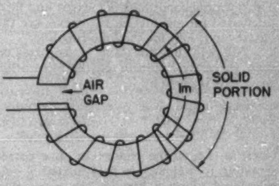

Fig. 7. Simplified magnetic circuit and exciting coil

The q_ν in equations 3 and 4 are roots of the equation

$$(k_l-1)q^2+2\frac{q\sin q+\cos q-1}{\cos q}-\frac{T_\beta}{T_0}=0 \quad (5)$$

and

$$\alpha_\nu=\frac{q_\nu^2k_l}{T_\beta/T_0} \quad (6)$$

Equations 3, 4, and 5 have been solved for numerical results using a leakage coefficient k_l of 1.15. These are plotted as func-

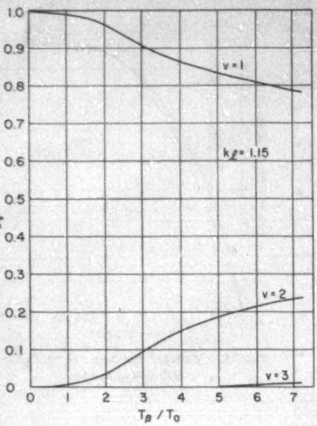

Fig. 8 (left). Coefficients for the flux equation

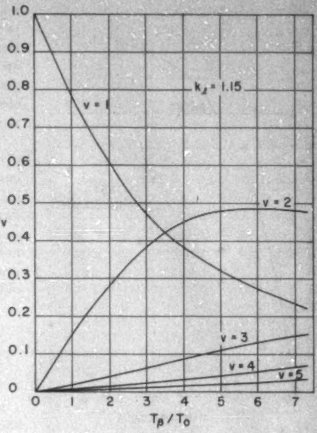

Fig. 9 (right). Coefficients for the current equation

tions of T_β/T_0 in Figs. 8, 9, and 10.

The ratio T_β/T_0 is calculated from the machine parameters as

$$\frac{T_\beta}{T_0} = \frac{l_m R}{4\left(\frac{a}{b}+\frac{b}{a}\right)\rho N^2} \tag{7}$$

The equations are derived on the basis of constant permeability of the magnetic circuit. To include the effects of iron saturation, the equations are applied as follows:

1. Approximate the machine's saturation curve by several straight lines; see Fig. 11.
2. The quantities ϕ_0, $\Delta\theta$, i_0, Δi, and T_0, have different values, corresponding to each straight-line portion of the saturation curve. The terminal conditions of current and flux, calculated for one line on the curve, are the initial conditions for the following line.
3. The field time constant T_0 decreases on each successive portion of the saturation curve. It is given by

$$T_0 = \frac{N}{R}\frac{\phi_1-\phi_2}{i_1-i_2}\times 10^{-2} \tag{8}$$

where $\phi_1-\phi_2$ is the change in flux corresponding to a change in field current, i_1-i_2, calculated along a line on the saturation curve.

Appendix II. Sample Calculations

A voltage response test was taken with an 8-pole, 165-kw, 600-rpm, 250-volt exciter. Machine constants are as follows:

a' = 20 inches
b' = 3.5 inches
k_l = 1.15
l_m = 12.6 inches
N = 250 turns per pole
R = 5 ohms per pole
T_β/T_0 = 7.25 seconds
$\rho = 5.91\times10^{-6}$ ohm-inches

The electric circuit arranged for test is shown in Fig. 12. The eight generator main-pole windings are connected in parallel. The circuit is initially at steady state.

Before closing the switch, the field current per pole is 2 amperes. From the saturation curve (Fig. 11) the initial flux per pole is 0.955 megaline. The initial linear relation, between flux and field current is useful up to 12 amperes, 5.7 megalines.

For this first region the following apply:

$T_0 = 250/5\times5.7/12\times10^{-2} = 0.238$ second
$k_l T_0 = 0.273$ second
$i_0 = 2.0$ amperes
$\Delta i = 252/5 - 2.0 = 48.4$ amperes
$\phi_0 = 0.955$ megalines
$\Delta\theta = 5.7\times48.4/12 = 23.0$ megalines

From Fig. 8 the ϕ_v are 0.783, 0.237, and 0.004. Referring to Figs. 9 and 10, the i_v are 0.225, 0.479, 0.151, 0.070, 0.034, and the α_v are 0.32, 1.82, 8.3, 13, and 23. Note that the negative exponents appearing in the fourth and higher order terms of the current and flux equations are large compared with the exponents in the first and second terms. Except for small values of time, deletion of the fourth, fifth, and higher numbered terms has no appreciable effect on the results.

The flux equation should be used only over a range between the end points of each straight-line portion of the saturation curve. Calculate the time required to reach the higher value of flux. Substitute this value of time in the current equation to find the corresponding current. This is the initial current, i_0, to be used in the current equation for the following straight-line portion of the saturation curve.

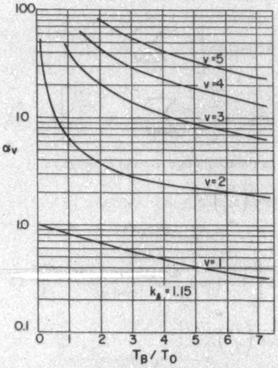

Fig. 10. Exponents for the flux and current equations

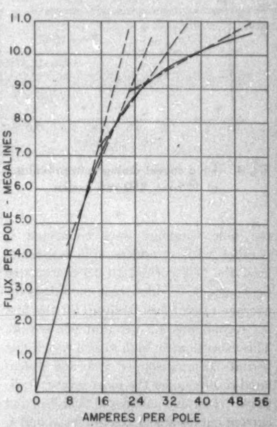

Fig. 11. Static saturation curve for 8-pole, 165-volt exciter

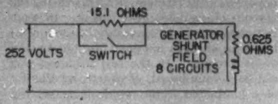

Fig. 12. Circuit arrangement for test

These calculations were carried out for four regions of the saturation curve. The results are shown in Figs. 3 and 4.

T_β/T_0 is the ratio of the solid frame time constant to the main-field time constant. Machines of standard design commonly have a T_β/T_0 equal to approximately 1.0. When calculating the performance of these machines, only two terms are needed in the flux and current equations. For v equal to 3 and greater the ϕ_v and i_v are small and the α_v are large, so these higher numbered terms become negligible.

Discussion

K. G. Black (General Electric Company, Schenectady, N. Y.): The authors are to be commended for obtaining a practical solution of a difficult and long-unsolved problem. They make use of a solution obtained by Dunaevskii (reference 1 of the paper) for the case of an unsaturated magnetic circuit containing a solid core of rhombic cross section and they assume that this circuit is a good approximation to the actual magnetic circuit in which the solid core is of rectangular cross section. Dunaevskii presents experimental data to demonstrate the similarity of flux responses, but for only one particular core. It is of interest to examine the validity of this approximation for other core dimensions.

The exact solution for a magnetic circuit with solid core of rectangular cross section is known for the case of flux decay, assuming the current drops to zero instantaneously. The flux decay of the exciter, for which the authors present machine constants, is calculated with the use of this exact solution. It is curve *D* of Fig. 13, and the flux decay as calculated by Dunaevskii's solution is curve *C*. For comparison with other approximations, the flux decay is calculated by two other methods. Curve *A* is based on the solution of Weber (see reference 3 of the paper) for a solid core of circular cross section, and curve *B* is calculated from a solution, suggested by Poritsky,[1] based on the assumption that the width of the frame is very large compared to the thickness. It can be seen that both curves *B* and *C* closely approximate the exact solution, curve *D*. The flux decay calculations were made on the basis of no saturation, the same basis on which the solutions were obtained.

Similar calculations were made for a 500-kw, 375-volt exciter and the results plotted in Fig. 14. The curves have the same general shape as those of Fig. 13, with the rhombic solution being the best approximation to out beyond 0.7 second.

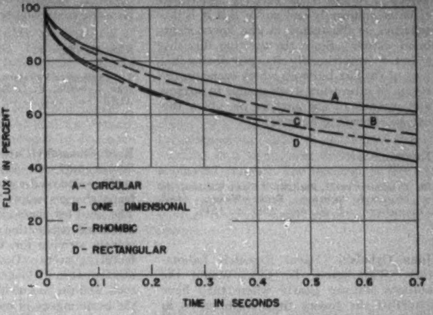

Fig. 14. Flux decay of 500-kw, 375-volt exciter

Examination of Figs. 13 and 14 lead to the conclusion that the authors are justified in proposing a method which is based upon the use of a rhombic core as an approximation to a rectangular core.

It may be noted from Figs. 9 and 11 that at the higher flux densities, and therefore in or near the region of saturation, the calculated flux build-up is more rapid than the measured build-up. This is particularly true of the 165-kw exciter. Such variance might be expected by reason of the manner in which Dunaevskii obtained his solution for flux build-up.

Dunaevskii separates the total flux into two parts; one part due to the exciting current and the other due to the eddy currents. He considers that the part due to the exciting flux is distributed uniformly across the cross section of the core. When all or part of the core is saturated, the actual flux distribution is considerably different from the uniform flux density used by Dunaevskii in his solution. If, when the core is saturated, the exciting flux could be separated from the eddy current flux, the exciting flux would be found to be distributed not uniformly, but with the highest density at the center of the core and the lowest density at the surface. This results in more eddy currents than if the exciting flux were distributed uniformly, and hence a slower build-up of flux.

Fig. 15 shows two flux build-up curves

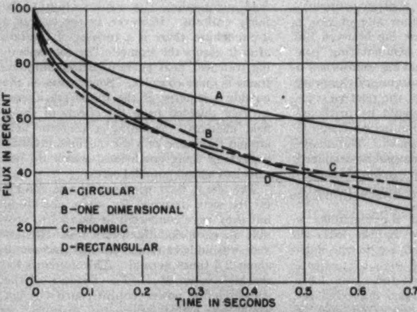

Fig. 13. Flux decay of 165-kw, 250-volt exciter

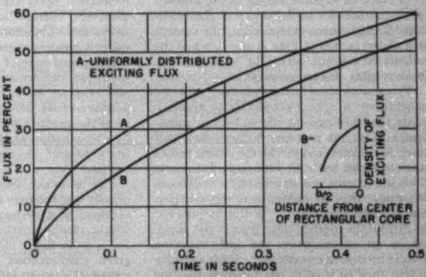

Fig. 15. Flux build-up in rectangular core

Curve A results if the exciting flux is distributed uniformly and curve B if it is distributed as illustrated in the lower right-hand corner. Since the exciting flux distribution is continually changing during that part of the flux build-up which occurs in the region of saturation, I am unable to suggest any method to the authors by which this can be taken into account.

1. *Discussion* by **H. Poritsky** of FIELD TRANSIENTS IN MAGNETIC SYSTEMS, **Ernst Weber.** *AIEE Transactions,* vol. 50, Dec. 1931, p. 1246.

John Cybulski (Naval Research Laboratory, Washington, D. C.): Would the authors indicate clearly where they have extended the theory that is presented in reference 1 of the paper? Essentially the difference appears to be that a no-load saturation curve can be approximated by several straight lines and that the terminal conditions calculated for one line on the curve are the initial conditions for the following line.

It is stated in the paper that assumptions 1, 4, and 6 are similar to those made in reference 1, which leaves the impression that assumptions 2, 3, 5, 7, and 8 are different. Then it is stated that the equations for flux and exciting current are derived on the basis of assumption 2. However, in Appendix I these equations for flux and exciting current, derived by Dunaevskii are listed and employed by the authors.

There is no specific reference made to the listed references 2, 3, 4 in the paper nor to any other material in the literature on eddy-current phenomena.

In Appendix II it is stated that machines of standard design commonly have a T_β/T_0 equal to approximately 1.0 inches. However, the listing of the machine constants for the sample calculation at the beginning of this appendix has T_β/T_0 equal to 7.25 seconds. Would the authors explain this difference?

It is indicated that this method can be extended to calculate the rise of commutating-pole flux during an increase in armature current. Will the authors comment on such an extension when the interpoles are solid rather than laminated? Would it still be possible to allow a mismatch of eddy currents; that is, to assume the eddy currents to be zero at the instant a new set of equations becomes effective?

Is there an explanation as to the absence of discontinuities in the slopes of the calculated flux curves as evidenced by the smooth calculated curves in Figs. 3 and 5, while the calculated current curves in Figs. 4 and 6 have visible discontinuities?

From work done in conjunction with d-c machinery[1] it appears desirable to approximate the eddy-current effects by an equivalent circuit. It was found that a field coil may be represented by the d-c ohmic resistance in series with an inductance element. This inductance was shunted by a resistance in series with an inductance, representing the eddy-current effect. Will it be possible to extend the method described in the paper so as to approximate the eddy current effects by equivalent circuit? Such a circuit might then be used in combination with an equation describing a no load saturation curve to calculate the flux and current response continuously.

1. TRANSIENT PERFORMANCE OF D-C MACHINERY, **John Cybulski, E. L. Brancato, J. P. O'Connor.** *AIEE Transactions,* vol. 72, pt. III, Feb. 1953, pp. 45–52.

R. M. Dunaiski (General Electric Company, Schenectady, N. Y.): Today's industrial applications of d-c machines are calling for faster changes in speed, current, and voltage. The need for these changes stems from the increased production that plants are constantly striving for, to offset rising manufacturing costs. Design engineers of d-c machines can no longer be content with their tools and the methods by which they gauge the performance of machines under steady-state operation, but must seek new methods with which to predict transient performance. The authors should be congratulated on providing just such a tool.

The calculation of the response of a d-c machine to impact excitation, based on eight simplifying assumptions which change the actual magnetic circuit into something having apparently little resemblance to a d-c machine, would be most questionable without experimental verification. Yet, for a variation of machine parameters over a range of about 10 to 1, the test results show fair agreement with the calculated curves. Improved correlation between calculated and test performance could undoubtedly be obtained by taking into consideration the variation in leakage flux as a result of saturation. This nonlinear characteristic, along with a better correlation of the geometric configuration of the frame, could be considered with the use of an appropriate numerical solution or some other method in lieu of the present approach to the problem.

The authors briefly mention the adaptation of their method of response calculation to the quadrature axis of a d-c machine. Here lies a fertile field for future work. The rapid advancements made in improving the response of control systems make it imperative that the machine design engineers know exactly what all their machine limitations are, and what is equally important, what can be done to improve the machine's performance. One such basic limitation, as far as improved response is concerned, is the maximum permissible rate of rise of armature current. For a given commutation margin the maximum rate of rise is dependent upon the time lag between the armature current and commutating pole field flux. Therefore, having established a desired commutation margin and knowing the required rate of rise, the relative commutation performance could be predicted and whether or not a laminated frame is justified could be determined. The analysis of the quadrature axis would be simplified by the omission of the saturable characteristics present in the excitation magnetic circuit.

The ultimate user of d-c machines is usually interested only in the over-all response of a system and not in the individual characteristics of each component. For a given figure of merit and, again, for a given commutation margin, improved response of a d-c machine can be obtained by reducing the eddy currents which tend to oppose any flux changes, or by increasing the amount of available field forcing. In some instances it may be necessary to use a combination of both methods to obtain the desired results. In the first instance, this can be accomplished, of course, by the use of a laminated frame which increases the cost of the machine. On the other hand, greater field forcing entails larger exciter capacity. It behooves the engineer to strike an economic balance between the two methods in order to insure a most economical system to the customer. The authors have provided the necessary tool with which this correlation can be made in the early stages of design.

Many engineering problems, practically unsolvable in the past, today are greatly simplified by the increased use of computer facilities. Predicting the response of a d-c machine to impact excitation is a good example of this kind of problem, and the paper should be a forerunner of many more to come destined to improve the art of machine and system design.

J. J. Brockman and **C. E. Linkous:** The authors wish to thank the discussers for their interest and their contributions toward a solution of the problem.

Mr. Black has presented an analysis and calculations to justify the substitution of a rhombic section for a rectangular one. He has also demonstrated the effect of saturation of the magnet frame.

Referring to Mr. Cybulski's comments, the authors wish to point out that Dunaevskii (see reference 1 of the paper) derives his solution for a magnetic circuit of constant permeability consisting of a solid part and a laminated part separated by an air gap. The authors have applied Dunaevskii's solution to the d-c machine and compared calculated results with experimental data.

Dunaevskii's solution for a rhombic section is in many respects similar to Weber's solution for a circular section (see reference 2 of the paper). Wagner has further modified Weber's solution by eliminating the equivalent of assumption 4 (see reference 4 of the paper).

Assumption 2, as applied to d-c machines, is much more inclusive than corresponding assumptions made by Dunaevskii and Weber. For example, in the case of a magnetic circuit with a toroidal core such as that in Fig. 7, but with a large radius of curvature, one would expect the transient field surrounding the solid section to be fairly uniform. However, in the case of a d-c machine, there is a turning of the flux after it enters the frame. The corresponding transient field pattern surrounding the frame is quite complex. Some areas on the outside perimeter of the frame are almost entirely shielded from the effects of shunt field changes. Assuming a uniform field around the frame of a d-c machine involves neglecting these conditions, which do not exist in a simple toroidal core.

The shunt field windings of the 165-kw exciter were designed for series operation, but they were connected in parallel to provide an exceptionally severe test. Resistance was added to limit the field current to about 2.5 times normal. This accounts for the high value of T_β/T_0. Because of the very high field power required, such a design would have little practical use.

The method can be extended to calculate

the rise of commutating-pole flux, including the effect of solid commutating poles. The authors have not considered its application beyond the linear range of the commutating-pole flux.

There are discontinuities in the calculated flux curves corresponding to those in the current. They are not so severe because the eddy currents influence the flux build-up much less than the field current. That is, for a given T_β/T_0, the $\phi_2, \phi_3, \phi_4, \phi_5 \ldots \phi_\nu \ldots$ terms of equation 1 of the paper are considerably smaller than the $i_2, i_3, i_4, i_5 \ldots i_\nu \ldots$ terms of equation 2.

A simple equivalent circuit for the shunt field is not readily derived from Dunaevskii's solution. Since this paper was prepared, a method has been under study to replace the effect of eddy currents by a short-circuited winding coupled to the shunt-field winding. Preliminary calculations agree very well with test results. If the method proves satisfactory, it will be described and submitted in a future paper.

Mr. Dunaiski points out that the desired response of a d-c machine may be obtained either by increasing the amount of field forcing with a solid-frame machine, or by laminating the frame. Except for very high rates of rise of main-field flux (e.g., 2.0 per unit flux per second and higher) the increase in forcing voltage required to overcome the eddy-current effect is small.

Mr. Dunaiski also calls attention to the effect of frame eddy currents on commutating-pole flux. A d-c machine should be designed to commutate satisfactorily the highest rate of rise of armature current frequently encountered in its application. If this rate of rise exceeds the commutating ability of a standard solid-frame machine, the designer may either design a solid-frame machine in a larger size, or he may use a laminated frame. The decision is one of economics, but from the user's point of view the oversized machine has the advantage of larger steady-state commutation margin.

Investigation of European Practices in Power Line Design

EDUARD FRITZ
MEMBER AIEE

IN EUROPE, power transmission cables and towers must resist, generally, the same natural forces of wind and ice as in America. It is just as necessary to consider the tension of cables at angles and at dead ends, the longitudinal pulls when ice or wind loads are not equally distributed between spans, and the exceptional case of rupture of a conductor or shielding wire.

The purpose of this paper is to review assumptions in connection with wind and ice, and other loading factors specified by European line designers, and where possible to make a comparison between American design assumptions and those employed abroad. Also included are some comments of European design requirements and the direction which changes might take. A short discussion of some of the European structural design practices differing from those in this country is also included.

Wind Pressure

The wind pressure exerted upon a conductor and transmitted to the towers is a function of the wind speed. A comparison[1] of wind speeds employed by European designers is not conclusive in connection with tower loadings because of the use of differing coefficients K in the pressure equation $P = KSV^2$, where S is the exposed surface and V is the wind speed per second. There is little disagreement in the coefficient K for flat surfaces. The variations lie in the reduction multiplier for pressures on cylinders. In this country 0.5 is used for bare cables and iced cables regardless of diameter, while in Europe the reduction multiplier varies from 0.4 to 0.7, and this variation applies with the cable diameter as well. In Germany, with emphasis on exactitude, the wind pressure coefficient first decreases with increasing diameters, then increases again to a value of about 0.5 for the larger cables. Some countries use larger values for poles and circular tower members as pipe than for conductors.

Several countries increase the unit wind pressure for spans and towers over 95 feet in height. In the light of recent failures of radio towers this 25-per-cent (%) increase seems a reasonable requirement for tall transmission towers. The low points of the conductors usually have the same ground clearance; thus it seems a refinement to increase the unit wind pressure on cables except, perhaps, for very high crossings.

The calculation of wind pressure on poles and towers is generally based upon the maximum wind speed anticipated. The peak velocity of a squall has a relatively narrow front, so a pole or tower might receive the full blast of it. However, the mean wind velocity in a long span is considerably lower than the recorded maximum velocity.

It was found in Swedish tests[2] employing 720-foot spans with a maximum velocity front width of 65 feet, that the corresponding average wind velocity of the entire span was 60% of the maximum velocity. In Sweden, as a result of this investigation and the current wind resistance K factor of 0.6 for cylinders, a unit wind pressure of 5.1 pounds per square foot is now specified on either bare or iced cables. This is but 25% of the 20.4-pound-per-square-foot pressure used for flat surfaces.

The 5.1-pound-per-square-foot unit wind pressure used is an average value which is exact for only one span length, 720 feet. For longer spans a lesser unit wind pressure might be used, as the mean velocity will decrease with increasing span lengths. The variation is probably unimportant but it suggests that steel towers on long spans might be designed for a lesser unit wind pressure than are wood poles of shorter spans. This is the reverse of American practice if an 8-pound pressure for steel is used after giving recognition to the overload factors and 4 pounds for wood.

For iced cables, some countries such as Italy use one-fourth of the unit wind pressure assigned bare cables because they consider that but half the maximum recorded wind speed will occur coincident with an iced condition. Italy is divided into three zones: plains, hills and mountains. In the plains and hills 16.4 pounds per square foot of wind are used for bare cables and 4.1 pounds when the cables are covered with 0.47 inches of radial ice. In the mountain zone 21.9 pounds is used for bare cable and 5.5 pounds for cables covered with 0.625

Paper 55-149, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 18, 1954; made available for printing November 30, 1954.

EDUARD FRITZ is with Day and Zimmermann, Inc., Philadelphia, Pa.

The Pennsylvania Water and Power Company made possible in 1953 the author's trip to Europe, and the preparation of this paper. The author is indebted to the European engineers who contributed much of the material from which the article is drawn, and to foreign representatives of the Copperweld Steel International Company and the Ohio Brass Company for their help in arranging conferences and acting as interpreters.

inches radial ice. The wind under the bare condition will govern in the structural designs of the larger lines.

A corollary to reduced wind pressures on wires is the resulting smaller swing angles of insulator strings toward the tower. It has been pointed out that greater tower weight savings can be realized by shortening crossarms through a reduction of assumed insulator swing angles than will result from an equivalent decrease in the number of insulators in the string. Several countries are at present giving this their attention, first, because it will permit upgrading or increasing the voltage use of existing lines if more units can be added to the string and, second, it will reduce the cost of new lines, particularly where the torque of a broken wire is considered.

The French have been conducting a series of tests[3] on insulator and cable deviations. These tests confirm the Swedish mean wind velocity values and the fact that wind is not constant throughout space and time. Actually, the wind action results at the insulator string in a figure which represents an average value with respect to space because of the length of the spans; and with respect to time because of the inertia and elasticity of the conductors. As a result of these studies maximum insulator swing angles in France in the future will be calculated for a transverse wind push of 4.9 pounds per foot for cables of more than 1/2-inch diameter, and 6.4 pounds for cables of less than 1/2-inch diameter. These values are one-third and one-half of the pressures established by French specifications for the calculation of tower stresses.

A maximum 30-degree swing angle is at present assumed in Switzerland in spite of the Swiss design requirement of a 10.2-pound-per-square-foot wind pressure on cables. There, the swing angle is confined to 30 degrees by a generous use of suspension weights.

To those who design wood *H* frames with smaller swing angles than are to be used for steel towers, it is pointed out that the American code specifies a 4-pound-per-square-foot crossline wind load for conductors of towers and poles alike. The overload applies only to the tower capability, not to the conductor swing. Perhaps for the shorter crossarm designs at poles, reliance is placed upon that section of code which permits 30-degree swings at wood but requires 45-degree swings at steel. When poles are fitted with metallic down leads it seems that insulator swings at poles or towers should be treated alike. Surely the workman is electrically safer inside a tower cage than on the side of a grounded pole.

In 1954 Bellaschi[4] suggested a reduction of electrical clearances at higher voltage lines as well as of insulator swing angles; and at the Poles, Towers and Conductors AIEE Subcommittee meeting, much discussion concerned the form the revised code should take. The European trend would favor reducing the design swing angle to 30 degrees, provided the code includes a definition of the horizontal and vertical forces to be considered, thus restricting the location of poles or towers to sites of sufficient vertical load so that swing angles of 30 degrees will not be exceeded. This can usually be accomplished by the addition of weights at insulators.

Ice Loads

Most countries of Europe[1] include in their designs an allowance for the accumulation of ice on the conductors. In about half the countries a 12-millimeter-radial (0.47-inch) is added, as in this country, and the remainder add a constant weight of 2 kilograms per meter (1.34 pounds per foot) without regard to the cable size. In mountainous regions and in particular conditions, ice loads as great as 12 kilograms per meter (8.05 pounds per foot) have been observed and are specified.

In Europe, no direct relationship is established for increasing ice thickness requirements in terms of elevation above sea level. However, Italy does assume increased ice formation in the mountain zone, as do Switzerland and France. Sweden is divided into two ice zones, with 0.95 inches specified for the interior; and 1.34 for the coastal region. Ice in Sweden is assumed to have a specific gravity of 0.75, whereas in this country 0.92 is assumed. This reduces the ice weights in Sweden to formations of about 3/4 and $1^{1}/_{4}$ inches in terms of the vertical loadings in this country. Norway has two icing districts 1/2 inch for the usual area and 1 inch for the lake area. In one special location Norway specifies a 5-pound-per-foot load for the largest conductor. When special ice formations such as 5 and 8 pounds per foot are used in Europe, they are applied as vertical loads and to determine wire tensions at angles and dead ends, and are not coincident with wind and broken wire loads.

Broken-Wire Loads

The European countries which take into account the longitudinal pull of a conductor or shielding wire are divided into four groups,[5] as follows:

1. Those which combine wind and broken wire forces, such as Germany.
2. Those which combine ice and broken wire forces, such as Sweden.
3. Those which combine wind, ice, and broken wire forces but do not add additional longitudinal pulls, such as Great Britain, Belgium, and Norway. (America is in this group.)
4. Those which combine wind and ice, and also include longitudinal pulls due to the unbalance in conductor tensions between spans caused by uneven wind and ice loadings. These longitudinal pulls are calculated either as a function of the span and overload of ice or wind, as in France, or are given a percentage of the conductor tension as in Italy.

In Switzerland are two types of design: those with a dead end every mile, which are treated as in Italy, and those without dead ends, where a wire is broken simultaneously with ice and wind loads.

A comparison of the influence of broken-wire loads upon tower weights is complicated by the varying combinations with vertical and transverse loads; the many conductor sizes and differing conductor tensions employed, and the use of overload factors. Until recently, England appeared to apply the greatest broken-wire load: 70% of the conductor design tension plus 50% overload. This is equivalent to 1.05 times the conductor tension at the tower elastic limit. In the latest 275-kv tower designs, however, but 10% overload was assigned in connection with broken wires. This is equivalent to 77% of the broken-wire value used in this country. Belgium assigns the conductor design tension at the tower elastic limit as the broken wire load, which is the load most in use, i.e., conductor tension with no overload when 8 pounds of wind are acting on cable covered with 1/2-inch radial ice. Germany applies 50% of the cable design tension at the tower elastic limit. No ice is considered when this load is applied.

In Sweden an English translation of the design practices[6] has been prepared which is worthy of consideration. To determine conductor pulls at corners and dead ends, the resultant is computed of the assumed wind and ice loads, and to this value, the term "weight of ice in the absence of wind" is assigned. The tensile stress set up in the conductors when subjected to this load plus 30% overload is used at corners and dead ends. In the design of lines erected with reinforced security the weight of ice in the absence of wind is never considered to be less than 1.34 pounds per foot. In America for cables larger than 7/16 inch in diameter the resultant of wind and ice loading is always greater than this value.

In the tower design for breakage of a cable, the tensile force is taken as 60% of that caused by the weight of ice in the absence of wind. This reduction is stipulated "because the mechanical design of supports is based on the same permissible tower stresses irrespective of whether the conductors are intact or broken, although the actual stresses may in reality be higher when the conductors are broken." Experience shows "that this method of design is adequate to insure the stability of supports, even in those cases where breakage of conductors takes place while the conductors are acted upon the full load of ice."

At first it would appear that 60% cable tension times 1.3 overload factor or 0.78 is the broken wire multiplier. This may be so for shielding wires rigidly connected but for conductors "due regard may be paid to the reduction of the tensile stress in the conductor which can be brought about by the deflection of a suspension insulator string; or by the bending of the support or the crossarm. In general, the reduction in the tensile stress, due to the deflection of standard suspension insulator string, can be assumed to be about 50%." 50% of 60% times 1.30 overload or 0.39 of the cable design tension is the broken wire load at the tower elastic limit used in Sweden for the 400-kv line. It is the practice to break one cable on a single circuit line, two on a double and so on. For the bundled conductor lines both cables per phase are broken. This seems to be the practice everywhere, when bundled cables are used. When in Sweden the intended third cable per phase is installed to the bundled lines, only two out of the three are considered broken.

Italy adds, as longitudinal load, about one third of each cable's design tension, at which load the structure is designed up to 90% of its elastic limit. Note that under this system of loading, no broken wire torque is considered. Or as an alternate one cable may be broken at 70% of its design tension.

In France a longitudinal pull is added for each cable. This pull appears to vary with the ice or wind load. A report of a recent French line indicates that the load of one broken conductor at 40% of conductor tension was applied. In this case the conductor tension was that resulting from the application of 14.6 pounds per square foot of wind load on the bare cable.

Table I. Strength Characteristics of Steel in Europe

Class	Ultimate, Psi	Elastic Limit, Psi
ST 37	52/64,000	28,400
ST 44	62/74,000	34,000
ST 54	74/88,000	40,000
	94/11,100	54,000 (in England)

Motor Columbus of Switzerland in their designs of towers employing pipe filled with concrete as structural members are adding as longitudinal pull 5% of the maximum cable tensions for each cable. When the Swiss apply a broken wire load, they choose a value of 50% of the conductor design tension. To this they add $12^{1}/_{2}\%$ overload, which is equivalent to 0.56 times conductor design tension at tower elastic limit.

There is general agreement in Europe that the supposition of a broken wire should be questioned, particularly when applied to high-voltage lines with large conductors. Conductor failures are indeed very rare and, if they are considered as being possible, it is believed that a unit stress near the structure elastic limit should be adopted without the inclusion of other loads.

Tower Design Features

Before passing on to the tower weight summary there are several primarily structural design features practiced in Europe which differ from American procedures. First is the use of high-tensile steels. Four grades of steel are available in Europe with strength characteristics as shown in Table I.

The prevalent practice is to design for *ST 44* steel which is nearly equivalent to the American grade *A 7*. When an oversized angle is required, as a 1/4-inch thickness, and 3/16 is available in a higher grade of steel, the 3/16 section is substituted. For redundants and low-stressed members the less expensive *ST 37* is used. Variably sized and high-strength bolts are often used in the same structure to avoid gusset plates, and to permit smaller structural angles. Where there is an advantage in having fewer gauge lines at the splice, or a lesser hole reduction at the diagonals, it is not unusual to find 3/4-, 5/8- and 1/2-inch-diameter bolts in the same structure. It is estimated that 15 to 20% tower weight savings result from these practices.

Steel fabrication is very competitive among the different countries of Europe, and the design and steel weight savings are largely passed on to the utility. The British are using 94,000-pound-per-square inch (psi) steel to good advantage. Towers employing this steel, now being fabricated by a British firm for a new 230-kv line in Norway, will weigh but 65% of those of an earlier American-fabricated Norwegian line, yet designed for lighter loads. Not all of this weight-saving is the result of the use of high-strength steel however, as other design innovations not practiced in this country are being followed.

Tower designers here generally consider tower struts as hinged members, while many European designers treat them as rigid or semifixed-ended. In Switzerland the first section of a tower, if connected to a stub embedded in concrete, is assigned a column length of 0.8 times the panel length, and for sections above the bottom section 0.9 of the panel length is used. Their code permits 0.7 and 0.8 for such members. Tests, they say, sustain these values when butt splices are used, but not the overlapping splices of this country. Diagonal and horizontal struts when attached by bolts in both legs, or welded, are designed as semifixed-ended, and only single-leg bolted members are considered as hinged.

A subject, of which there seems to be agreement in Europe, but which in America is treated quite differently, is the torque distribution from a broken conductor at the end of a crossarm. If a tower has a square cross section, it is considered, here and abroad, that the torsion is divided equally on all four faces, provided that at the applied torsion level, there is a plan bracing of adequate strength, and the four tower faces have equal rigidity. For towers having a rectangular cross section, there are an infinite number of cases between square and straight line, with torsion distribution dependent in each case upon the relative dimensions of the transverse and longitudinal face and on their relative rigidity.

The British treatment of a rectangular tower as described by A. E. Percivall[7] is to consider the crossarm as a rigid beam with the torsional reactions taken entirely by the longitudinal faces. An American method, commonly used, divides the torsion equally on the four faces, but at an increased value over the square tower value depending upon the tower's width-length ratio. The British method permits thinner tower tops along the line, and results in narrow waists and tower spreads. It places all the torque above the waist in the shorter longitudinal faces, whereas in the American treatment much of the torque stress goes in the wide transverse face with its long 1/r's. It is said that the 5 to 10% lighter towers result from the British treatment.

Table II. Tower Weight Estimates

230-Kv Single-Circuit Suspension Towers; 1,300-Foot Span; Three 795,000-Circular-Mil 26/7 Steel-Reinforced Aluminum-Cable Conductors, T=11,500 Pounds; Two 7/16 Copperweld Shielding Wires, T=6,500 Pounds

† Overload factor.

With reference to the pipe-filled concrete tower designs offered by Motor Columbus of Switzerland,[9] not all of the reported savings "up to 1/2 to 2/3 of the weight of steel contained in the normal angle iron structure" are the result of the substitution of pipe and concrete. They make at least three other departures from American practice which also contribute to the weight savings: 1. the use of guys for tension members; 2. thin-walled pipe sections, 3/16-inch minimum thickness not specified; and 3. treatment of legs and struts as fixed-ended or semifixed-ended. However, much weight-saving results from the use of round sections which have better buckling resistance than angles, and the substitution of concrete for steel to support the compression load. Motor Columbus in their designs, assign a proportion of the compression load to the concrete on the basis of a steel-concrete modulus ratio of n equals 10. Their tests of field-poured concrete in pipe columns would support the use of an n ratio of 7 or even 5.

Some extra steel weight in our towers is due to our 3/16-inch minimum thickness requirement, which is intended to insure long tower life. In Italy it is felt that the emphasis should be on more adequate protective coatings rather than on the thickness of the underlying steel because the added costs of heavier than 2 ounces per square foot of galvanizing is slight, and added life through better and heavier protective coatings is not only possible, but will permit original savings of 7 to 15%, and will delay the first painting date.

Also, in Italy pipe in the towers has been used. One application was to use angle sections as corners and pipe as bracing. The pipe was flattened on the ends and bolted directly to the legs. At present, this type of construction is limited to painted structures as the inside of the pipe cannot be galvanized after flattening, and the flattening process will damage galvanizing if applied first.

Weight Comparisons

A simple tabulation of wind and ice loads is not conclusive of whether or not European design requirements lead to heavier structures than those of America. Such a listing only reveals where emphasis is placed; on wind, ice, or longitudinal pulls with or without torsion, and not the effect of coincidental load combinations and at varying overloads. Neither is a comparison of the weights of actual towers used in any voltage class conclusive, because of varying cable sizes and stringing tensions employed, and the difference in phase spacings and electrical clearances. The grades of steel available, the shape of the structure, and the knowledge and experience of the designer also leave their marks on the final tower weight.

For comparative purposes the Peterson empirical equation[10] was employed to arrive at an estimated weight for the towers of each country, using the load conditions applicable. The equation is

$$W=KHe\sqrt[3]{P^2}$$

where

He = effective height of the tower or center of gravity of the cable loads above ground

P = resultant of the cable pulls under maximum loading conditions

K = empirical constant which varies between 0.25 and 0.35 and is dependent upon the tower form

This equation is a convenient tool for evaluating the effect of changing loads on tower weights, as it states that a tower weight is proportional to its effective height and exponentially proportional to its unbalanced pulls. In each case the weight calculated is that of a 230-kv suspension tower on a 1,300-foot span without angle in the line.

For the American towers, a range of tower weights is offered, each calculated by the Peterson equation using 8 pounds of wind as crossline load acting on radial ice formations varying from 1/2 to 1 1/2 inches. Each of these climatic loading conditions is coupled with a broken or unbroken conductor condition and with the several overload capacity factors employed by utility line designers, and designers of the government agencies.

In Table II are shown these calculated tower weights. By comparing the weight of a tower meeting a European country's design requirements with an American tower of similar weight at the top of the table, one can determine to what loads, by American standards, a tower of that weight might have been designed. For instance, an American tower designed to meet the requirements of our National Electrical Safety Code[11] compares in weight favorably with the Swedish designs for the hills area.

◆

Discussion

C. L. White (Bethlehem Steel Company, Bethlehem, Pa.): In this interesting paper various practices have been carefully reviewed and condensed into usable information for the transmission tower designer.

There seems to be a decided trend toward the use of a smaller number of insulator units in the string because of increased knowledge of insulation and flashover lightning information. Also, more study is now being given to the insulator swing angles under wind-loading deflections. This combination results in shorter crossarms and corresponding reduction in the torsion-loading on the towers from broken-wire conditions.

A few years ago, it was the practice to assume one-third of the number of wires to be broken for line-loading conditions. This resulted in designing for any two broken wires for the double circuit towers and for any one wire for single circuit lines. There is now a trend toward considering only one broken wire for double circuit towers as being satisfactory for most conditions of service.

Silicon steel appears to be the only higher strength of steel sometimes used for the construction of towers in eastern United States. This higher strength of steel is seldom used for parts other than for corner posts and then only on especially heavy structures.

American fabricating shops, in general, prefer to retain the same size of bolts throughout the same structure. Bolts of different sizes require additional operation and odd-hole punching in the shop which usually costs more than the tower weight-savings indicate. The additional handling and odd-sized hole-punching operations will also materially reduce the shop capacity. Shipments would be correspondingly delayed becaused of this feature. We also desire to use the same sized ladder or step bolts as used for the connecting bolts in order to retain the same punching for this item. United States fabricators use duplicating punch equipment which makes it economically impossible to change the size of bolt holes.

The practice of considering end-fixation factors when designing to certain unit stress values is usually well understood by the designer. The end-fixation factors are often included as a part of the specified unit stress, i.e., they are taken into account when establishing the unit stress values or the factors are applied to the unit stress values to suit the type of end-fixation for each type of member.

The distribution of torsion in a tower with a square cross section, such as exists in the usual double-circuit tower, wherein the four faces of the tower have equal rigidity, seems to be the general practice to divide the torque equally over the four faces of the tower.

In the case of single-circuit towers having a rectangular cross section in the plane of the crossarm, torsion is often distributed quite differently by various designers. Sometimes the torsion is distributed over the two parallel line faces. On other occasions, particularly with the waist-type and rotated-waist-type towers, where there is a square cross-section configuration below the waist, the torsion is distributed over the two parallel line faces down to the waist line and is then distributed equally over the four faces, if they have equal rigidity. We believe that a more exact torsional distribution is to distribute the amount of torsion to each tower face in direct proportion to its distance from the vertical axis of the tower. This will involve considerably more design effort than the procedure mentioned first.

The use of a minimum thickness of material of 3/16 inch, which is now quite prevalent, instead of 1/8 inch which was used in the past, is largely attributed to the heavier construction now required because of higher voltages, larger conductors, and longer spans. There are very few members in such towers carrying stress which can be less than 3/16 inch thick in order to satisfy strength requirement. Another factor is that angles of over 2 by 2 inches in size cannot now be obtained in thicknesses of less than 3/16 inch; while formerly much larger angles could be obtained in 1/8-inch thickness.

We agree with the author in regard to the desirability of a heavier zinc coating on transmission towers. We have no difficulty in our galvanizing shop, in obtaining on structural materials an average weight of zinc of 2.75 ounces per square foot and a minimum of 2.5 ounces per square foot, which weights are in excess of those generally specified. In regard to galvanized bolts, we usually obtain a 1.65-ounce-per-square-foot average and a minimum of 1.5 ounces per square foot, which are also in excess of the weights normally specified.

Carl Schofer (Pennsylvania Power & Light Company, Allentown, Pa.): On Sunday, September 19, 1954, at 9:01 p.m., a tornado type of storm of severe intensity crossed the Sunbury-Siegfried 220-kv line at two locations approximately 3 miles apart causing towers numbered 39/7, 40/1, and 43/2 to collapse. The intensity of the storm can be visualized from the damage done in the vicinity of tower no. 43/2 where, in a heavily wooded area down the mountainside from the tower, a path approximately 100 feet in width was torn through the timber. Trees varying in diameter from 16 to 30 inches were uprooted and thrown to the ground, indicating the high velocity of the wind.

Towers numbered 39/7 and 40/1 are adjacent towers located in a terrain practically void of trees and covered mainly with low brush and small scattered scrub pines. The vegetation therefore did not readily indicate the high velocity of the wind. However, when consideration is given to the damage done to the line, it is quite evident that the storm exerted tremendous pressure in this area. Calculations indicate that a wind velocity of approximately 170 miles per hour would be required to stress the towers to their design limits or failure point under the conditions existing at the time the collapse occurred.

The three towers involved were 4-legged steel-framed structures normally used on tangent construction on 220-kv lines. The terrain throughout this area has an elevation of approximately 1,600 feet above sea level, at which elevation heavy ice loads are anticipated during the sleet season. The line was therefore designed to withstand a 25% greater load than that which would have been imposed on the structure by 1.5 inches of radial ice on both tower and conductors with a wind pressure of 8 pounds per square foot.

This section of the line on at least two previous occasions had been loaded with $2^1/_4$ inches of radial ice on both towers and conductors with a 10 to 15-mile-per-hour transverse wind and neither the conductors nor the supporting tower showed signs of excessive loadings after the storm had subsided.

During the windstorm of September 19, tower no. 40/1 when torn loose from its foundations turned through a vertical somersault and then executed a horizontal half-roll wrapping, itself in the power conductors and overhead ground wires. When the tower finally came to rest, it was approximately 100 feet east of its foundation and about 50 feet to the right of the center line of the right of way. When it is considered that a tower of this type weighs approximately 13,000 pounds without considering the weight of the power conductors or overhead ground wires, then it can be visualized that the storm was one having wind pressures far in excess of the original design loads considered. It is therefore quite apparent that the wind velocity was considerably greater than the calculated 170 miles per hour required to bring the tower to its failure point.

Neither power conductors nor the overhead ground wires were broken by the failure. The conductor suspension clamps on the insulator assemblies on all collapsed towers slipped along the wire stripping the aluminum strands from the steel core until the tower came to rest. In the case of tower no. 40/1, this condition exerted a tremendous impact on the adjoining tower no. 39/7, causing it also to collapse.

One outstanding point regarding the design of these towers brought to light by this failure is that the diagonal lacing members on the various leg extensions which run from the tower footings to the center line of the transverse and longitudinal faces of each tower are normally under a tensile load for all conditions of tower loading and are designed as tension members. The tension load is impressed on these members by the vertical weight of the tower and the attached conductors. Transverse winds impose a small compressive load on the same members. However, under no combination of loads is this compressive load high enough to cause a change in compression members. However, during the storm the cyclonic action of the wind endeavored to lift the towers vertically from their foundations, thereby eliminating all the vertical weight while at the same time exerting a high transverse wind pressure. The load on these members then changed from a tensile to a compressive load and the towers collapsed.

Erling Ringstad (Copperweld Steel International Company, New York, N. Y.): Mr. Fritz's talks before groups of engineers in Europe created a great deal of interest. It was a fine opportunity for the European engineers to learn about American engineering practices, to compare these with their own, and to discuss reasons for differences of design, etc.

The paper should prove equally helpful to engineers in this country and Canada to give them a better understanding of European practices. It was of particular interest to me to learn about the Swedish investigation covering the narrow front of maximum wind velocity and how this is applied in the design of lines, particularly of long-span lines. This particular point and many others should be of great interest to American designers.

It was a pleasure for my company to assist Mr. Fritz in making some of his engineering contacts in Europe and we shall be similarly pleased to help other American and Canadian engineers who plan similar visits to study European engineering practices.

Eduard Fritz: I should like to express my pleasure at the interest which my paper has aroused. My position is that of an investigator relating what has been seen and read, and not of one who takes the view that all European practices are better than those in America. I do feel, however, that the practices mentioned in the paper are worthy of our consideration.

Mr. White's remarks on the fabricating shop practices in his company and the types of steel available emphasizes that often there are good reasons for the differences in practice here and abroad. The second Bethlehem method of distributing torsion in a tower is the American procedure described in the paper. Mr. White's method of recognizing fixation through an adjustment of unit stresses illustrates the point that we sometimes reach the same end but by a different route. As to minimum steel sections in our larger towers there remain many redundants without stress which could be of lighter weight were it not for our minimum section requirement.

I wish to thank Mr. Shofer for his description of the tower failures which occurred during what surely was a wind storm of tremendous pressure. It is apparent from his description of the damage done to the adjacent wooded area, that the storm had a rather narrow front, which confirms the Swedish test referred to in the paper. Those who would eliminate broken wires in our designs must not overlook the fact that when a wind of high pressure and narrow front is concentrated in one span there is always a difference in conductor tension at the adjacent towers as the slack cable in the adjacent spans is drawn into the span of heavy wind. Thus a longitudinal force including great impact is exerted at the cable supports of the adjacent towers and we have in effect a broken-wire pull of not one but several wires. In both France and Italy this is recognized when a longitudinal force in the suspension tower designs is included. However, the longitudinal forces used are not of a magnitude to withstand Mr. Shofer's tornado.

A General Transmission Loss Equation

E. D. EARLY

THE relative simplicity of the familiar quadratic form of the transmission loss equation

$$P_L = \sum_m \sum_n P_m B_{mn} P_n \qquad (1)$$

as developed by George,[1] Eaton, Ward, and Hale,[2] and Kirchmayer and Stagg[3] is made possible by four basic assumptions stated in reference 3. Some of these assumptions have been found to be the source of serious error when this simplified form of the loss equation is applied to power systems where conditions are not in agreement with the assumptions.[4] This loss equation will be referred to herein as the simplified loss equation.

It is the purpose of this paper to develop an expanded form of the loss equation, which will be referred to herein as the general loss equation, and a method of determining the values of the equation's constants which does not require any of the foregoing assumptions. Accuracy of total system loss and incremental loss values of the various sources given by this general loss equation is not adversely affected by substation loads that vary at rates which differ from each other and from the rate at which the total system load varies. Neither is it affected by variation in the ratio of reactive power to real power required to be produced at each of the various power supply sources to maintain desired voltage levels as total system load varies between maximum and minimum. (A power supply source may be a generating plant, an interconnection, a large nonconforming load, or two or more of these located close together and treated as a single source.)

Paper 55-90, recommended by the AIEE System Engineering Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 19, 1954; made available for printing November 18, 1954.

E. D. EARLY and G. L. SMITH are with Southern Services, Inc., Birmingham, Ala., and R. E. WATSON is with the Leeds and Northrup Company, Philadelphia, Pa.

The authors wish to acknowledge the substantial assistance given by H. R. Koen and R. O. Usry in the preparation of material for this paper.

To achieve the foregoing objectives, the simplified loss equation must be expanded to include additional terms. Increased difficulty in solving this more complex problem may have been a factor in preventing such development previously. The application of this new method yields equations which are readily solvable on an analogue computer. A new analogue computer has been developed,[8] which quickly evaluates the incremental transmission loss and determines the incremental cost of power delivered, thus permitting economic loading of the power system.

Form of General Loss Equation

Both total transmission loss and incremental loss of each of the power supply sources are determined jointly by the load pattern (distribution of total system load by substations) and by the distribution of system power supply by sources. The simplified form of the loss equation properly reflects the distribution of power supply by sources, but it is based on the assumption that the load pattern remains unchanged as total system load changes, i.e., each substation load remains a constant fraction of the total system load.

The assumption that all substation loads vary at the same rate with respect to variation in total system load can result in substantial error when the simplified form of the loss equation is used on systems whose substation loads do not vary in this manner. For illustration, take a system consisting of two areas connected by transmission lines with a peak period load of 500 megawatts (mw) in each area and let it be assumed that load variation in the two areas is such that, when total system load is 600 mw, the load in area *A* is 250 mw and the load in area *B* is 350 mw instead of 300 mw in each area, which would be the case if the loads in the two areas remained a constant fraction of the total system load. When system power supply is such that 100 mw are being transferred from area *A* to area *B*, the simplified form of the loss equation would compute total system loss and incremental loss of each source on the basis of transferring approximately 50 mw from area *A* to area *B*, since this equation is based on the assumption that the loads in the two areas would remain equal, or 300 mw in each area. Since on most systems there is a substantial variation in the load factor of various areas, depending on the type of load supplied, industrial, commercial, or residential, and on the type of industrial load served, it is apparent that results given by the simplified form of the loss equation, which is based on the assumption that all substation loads vary in the same manner, may be inaccurate.

Under the assumption that all substation loads remain a constant fraction of the total system load, all substation loads will become simultaneously equal to zero when the total system load is reduced to zero. Under this condition, there will be no flow of power in the transmission system, power supplied by each source will be zero, total transmission losses will be zero, and the incremental loss of each of the sources will be zero.

If each of the substation loads varies at a different rate, one load will become zero before any of the others as total system load is reduced. If these rates persist as system load is further reduced, some loads will become negative. When the net system load becomes zero, the negative loads will be equal to the positive loads, and the negative loads, which may be considered as sources of power supply, will supply power equal to the requirements of the positive loads. Under this condition, transmission losses resulting from the transfer of power from negative loads to positive loads would be supplied by system generating plants. If the net system load is further reduced until the total of the negative loads exceeds the total of the positive loads by an amount equal to the transmission losses resulting from transferring power from negative loads to positive loads, no power supply will be required from the system generating plants. This condition will be termed and referred to herein as the condition of zero system power supply.

Under the condition of zero system power supply, there will be transmission losses and, consequently, an incremental loss value for each of the power supply sources. Each term of the simplified total loss equation is a constant multiplied by the product of the outputs of two power supply sources or the square of the output of one such source. Consequently, total system losses given by the simplified total loss equation under the condition of zero power supply will be zero since the output of all power supply sources is zero, this being correct only if all loads remain a constant fraction of the total system load as it is reduced to zero, which was one of the assumptions made in deriving the equation. To make this equation applicable to the general case where all loads may vary at different rates requires the addition of a constant term K_{L0} representing total system losses under the condition of zero system power supply.

Each term of the incremental loss equations, obtained by taking the partial derivatives of the simplified total loss equation, is a constant multiplied by the power output of one of the power supply sources. Consequently, these equations will give zero as the incremental loss of each of the power supply sources under the condition of zero system power supply, which is correct only for the condition where all loads vary at the same rate with respect to variation of the total system load. To make the incremental loss equations applicable to the general case where all loads may vary at different rates requires the addition of a constant term B_{n0}, representing the incremental loss of each source under the condition of zero system power supply to each of the incremental loss equations. The general form of these equations then becomes

$$\frac{\partial P_L}{\partial P_n}=\sum_m 2B_{nm}P_m+B_{n0} \qquad (2)$$

Collectively, the incremental loss equations for all power supply sources given by equation 2, which represent all of the partial derivatives of an unknown equation, become a partial derivative system which can be solved to obtain the total transmission loss equation in its general form, which is

$$P_L=\sum_m\sum_n P_mB_{mn}P_n+\sum_n B_{n0}P_n+K_{L0} \qquad (3)$$

where K_{L0}, the constant of integration, represents total system losses under the condition of zero system power supply. The partial derivative of equation 3 gives equation 2.

It will probably be possible to determine the values of constants K_{L0} and B_{n0} from a network analyzer study of the condition of zero system power supply. Pending development of the technique of making such a network analyzer study with the required degree of accuracy, another method of determining the value of these constants will be presented. A method of determining incremental loss values for each source directly from network analyzer data will be presented later in the paper.

The importance of including the constants B_{n0} and K_{L0} in the general loss equation may be obscure since the condition of zero system power supply is an imaginary condition. However, these terms respectively give the intercepts of the incremental loss and total loss equations at zero system power supply, and B_{n0} is essential to give the proper slope to the incremental loss equation when loads vary at different rates. In this re-

Table I. Procedure for Setting Up Normalized Equations

Case	(1) B_{11} +	(2) B_{22} +	(3) B_{12} +	(4) B_{10} +	(5) B_{20} +	(6) K_{L0} =	(7) Answer

	0	$2P_2$	$2P_1$	0	1.0	0	$(\partial P_L)/(\partial P_2)$
	P_1^2	P_2^2	$2P_1P_2$	P_1	P_2	1.0	I^2R
3	$2P_1$	0	$2P_2$	1.0	0	0	$(\partial P_L)/(\partial P_1)$
	0	$2P_2$	$2P_1$	0	1.0	0	$(\partial P_L)/(\partial P_2)$
	P_1^2	P_2^2	$2P_1P_2$	P_1	P_2	1.0	I^2R
4	$2P_1$	0	$2P_2$	1.0	0	0	$(\partial P_L)/(\partial P_1)$
	0	$2P_2$	$2P_1$	0	1.0	0	$(\partial P_L)/(\partial P_2)$
	P_1^2	P_2^2	$2P_1P_2$	P_1	P_2	1.0	I^2R

Values of P_1, P_2, $\frac{\partial P_L}{\partial P_1}$, $\frac{\partial P_L}{\partial P_2}$, and I^2R are known quantities for each case.

$\Sigma 1\times 2$ represents the summation of each entry in column 1 multiplied by the corresponding entry in column 2

$\Sigma 1\times 1$ represents the summation of the square of each entry in column 1

$\Sigma 1\times 1B_{11}+\Sigma 1\times 2B_{22}+\Sigma 1\times 3B_{12}+\Sigma 1\times 4B_{10}+\Sigma 1\times 5B_{20}+\Sigma 1\times 6K_{L0}=\Sigma 1\times 7$

$\Sigma 2\times 1B_{11}+\Sigma 2\times 2B_{22}+\Sigma 2\times 3B_{12}+\Sigma 2\times 4B_{10}+\Sigma 2\times 5B_{20}+\Sigma 2\times 6K_{L0}=\Sigma 2\times 7$

$\Sigma 3\times 1B_{11}+\Sigma 3\times 2B_{22}+\Sigma 3\times 3B_{12}+\Sigma 3\times 4B_{10}+\Sigma 3\times 5B_{20}+\Sigma 3\times 6K_{L0}=\Sigma 3\times 7$

$\Sigma 4\times 1B_{11}+\Sigma 4\times 2B_{22}+\Sigma 4\times 3B_{12}+\Sigma 4\times 4B_{10}+\Sigma 4\times 5B_{20}+\Sigma 4\times 6K_{L0}=\Sigma 4\times 7$

$\Sigma 5\times 1B_{11}+\Sigma 5\times 2B_{22}+\Sigma 5\times 3B_{12}+\Sigma 5\times 4B_{10}+\Sigma 5\times 5B_{20}+\Sigma 5\times 6K_{L0}=\Sigma 5\times 7$

$\Sigma 6\times 1B_{11}+\Sigma 6\times 2B_{22}+\Sigma 6\times 3B_{12}+\Sigma 6\times 4B_{10}+\Sigma 6\times 5B_{20}+\Sigma 6\times 6K_{L0}=\Sigma 6\times 7$

spect they are equivalent to the zero-output intercept of the familiar turbogenerator input-out curve which represents the heat input to the turbine at zero output. The value of constants B_{n0} and K_{L0} is determined by the relative rates of change of the various loads and is zero when all loads change at the same rate. Constant K_{L0} is always positive but B_{n0} may be either positive or negative. In general, B_{n0} will be positive when the loads normally supplied by source n are negative under the condition of zero system generation and will be negative when such loads are positive under the condition of zero system generation.

Method of Determining Value of Loss Equation Constants

It has been shown that the simplified loss equation can be expanded so as to cover the condition where loads vary at different rates. To eliminate the other three assumptions on which the simplified loss equation is based, as stated in reference 3, it is necessary to use an entirely different method of determining values for the general loss equation constants. This method will be outlined, then explained and illustrated in detail. The procedure is as follows:

1. A number of cases representing different system load supply conditions must be set up on the network analyzer and the following readings taken: Scalar value of line currents; bus voltage phase angle between each power supply source and each load; and transfer impedance from each power supply source to each load; see reference 4.

   The number of cases studied must not be less than $(n+2)$, where n represents the number of power supply sources, of which one-half should be for peak period load conditions and one-half for valley period load conditions. Each power supply source should be operated at maximum capability and at minimum capability, or at zero output, in one case for peak period loads and one case for valley period loads. Interconnections should be operated at maximum input to the system and at maximum output from the system.

2. The system I^2R loss for each case and value of incremental loss for each power supply source for each case must be computed. The method of computing incremental loss values from voltage phase angles between power supply sources and loads and relative rate of change of each load will be given later in the paper.

3. Equations for total system loss and incremental loss for each power supply source for each case must be set up, using the loss equation constants as the unknowns and the appropriate values of P_m and P_n as the coefficients. Since there will be n incremental loss equations and one total system loss equation for each case and $(n+2)$ cases, the total number of equations will be $(n+2)(n+1)=n^2+3n+2$, which is twice the number of unknowns, the loss equations constants.

4. The next step is to solve the equations for the values of the unknown loss equation constants. Since there are twice as many equations as unknowns, the equations must be normalized to obtain equations equal in number to the number of unknowns. The solution of these normalized equations provide a loss equation by which incremental and total losses may be computed that are in best agreement with the known values in the sense of least squares. The procedure for setting up the normalized equations for a 2-source system is illustrated in Table I.

It should be noted that the loss equation constants determined in the foregoing manner tie into incremental loss values for each power supply source and system I^2R loss for both peak period and valley period loads for $(n+2)$ cases selected to cover a wide range of system power supply conditions.

With 13 sources, the number of simultaneous equations to be solved is 105. The most advanced type of electronic digital computer offers the only feasible means of solving such a large number of equations for a reasonable expenditure of time and money. Solution of the equations is simplified by the fact that the normalized equations are symmetrical. The cost of solving 100 symmetrical equations is from $1,000 to $1,500 depending on the dominance of the diagonal terms. Use of less advanced computing equipment may cost considerably more even though the hourly equipment rental is less.

Effect of Rate of Load Change on Incremental Loss Values

Distribution of load by substations and distribution of power supply by sources are important factors in determining system I^2R loss and incremental loss values of each power supply source since these factors determine the flow of power in each transmission line. Not so generally recognized is the fact that the relative rates at which the various substation loads change with respect to a change in total system load is also an important factor in determining incremental loss of each power supply source; in fact the authors have seen no reference to this important principle in the literature. That the relative rate of change of each load does affect the incremental transmission loss of each power supply source is apparent, since the incremental change of the various loads determines the incremental change in the loading of the various transmission lines which, in turn, is one of the factors that determine the incremental loss of each power supply source.

The importance of rate of change of the various loads upon incremental loss values can be readily demonstrated by a simple example. Take the system shown in Fig. 1(A) consisting of a single generating plant and two loads, each of which is 150 mw, supplied over separate lines. The I^2R loss is computed to be 20.91844250 mw. Now let the total power delivered to the load be increased by 0.1 per cent, or 0.30 mw, and let this increase be divided between loads no. 1 and no. 2 so that each load is increased by the same 0.1 per cent, or 0.15 megawatts, which will maintain each load as a constant fraction of the total system load. Line flows for this condition are shown in Fig. 1(B). The I^2R losses are computed to be 20.96262788 mw, an increase of 0.04418538 mw for a 0.30-mw increase in total load supplied. The ratio of increment of loss to increment of generation is therefore

$$\frac{\Delta L}{\Delta P}=\frac{0.04418538}{0.30+0.04418538}=12.838 \text{ per cent}$$

In a like manner, the ratio of increment of loss to increment of generation when loads supplied are decreased by 0.1 per cent can be computed to be 12.824 per cent. The true incremental loss, which lies between the two ratios of increment of loss to increment of generation, cannot be more than 0.007 per cent different from the average of the two ratios, namely, 12.831 per cent.

Incremental loss computed in the foregoing manner will be found to be 15.648 per cent when 75 per cent of the total load change is at load no. 2 and 25 per cent at load no. 1. When 75 per cent of the total load change is at load no. 1, the incremental loss, computed in the foregoing manner, will be found to be 9.820 per cent. If load no. 1 is a 100-per-cent load-factor load and the total system load change is taken by load no. 2, the incremental loss of the generating plant will be 18.288 per cent, but if load no. 2 is the 100-per-cent load-factor load, the incremental loss will be only 6.593 per cent.

The wide spread of incremental loss values (6.593 to 18.288 per cent) for a given distribution of load and generation illustrates the important effect that the ratio of total system load change taken by each substation load, which may be quite different from the relative size of the loads, has upon incremental loss values. It also illustrates another important principle; namely, that, even though the simplified loss equation gives the correct total system loss, there is no assurance that partial differentiation will give correct incremental loss values since there are innumerable combinations of incremental loss values for the various power supply sources, depending upon the rates of change of the various loads, that will give the same total system loss. On the other hand, partial differentiation of the general loss equation may give correct incremental loss values for a given case even though the total system loss given by it is inaccurate because of the different effect the constants B_{n0} and K_{L0} have upon incremental loss and total loss. Constant K_{L0} has no effect upon incremental loss values and constants B_{n0} have a greater effect upon total loss than upon incremental loss, as illustrated by the following relationship between incremental loss and total loss

$$L=\sum_n \frac{1}{2}\left(\frac{\partial P_L}{\partial P_n}+B_{n0}\right)P_n+K_{L0} \qquad (4)$$

In addition, any inaccuracy in the determination of the value of the B_{n0} constants would be offset to a large extent by compensating changes in the value of the B_{mn} constants in so far as incremental loss values are concerned. It should be emphasized that, in the economic loading, accuracy in calculation of incremental transmission loss is of prime importance, whereas accuracy in calculation of total transmission loss is of secondary interest.

This method for determining incremental loss values will be used later in the paper and will be referred to as the $(\Delta L)/(\Delta P)$ method. Since this method uses the difference between two large numbers, all computations will be carried out with the same high degree of accuracy as that used in the foregoing illustration. In computing incremental loss in the aforementioned manner for a large number of cases, it can be stated from experience that incremental loss values computed by the $(\Delta L)/(\Delta P)$ method, when expressed as a ratio, will be correct within ±0.0003.

Method of Determining Incremental Loss Values from Network Analyzer Data

The method of determining incremental loss values for the various power supply sources from network analyzer data for use in setting up the simultaneous equations employed in determining the loss equation constants, as previously outlined, is based upon the voltage phase-angle method of determining the incremental loss incurred in transferring an increment of power from one generating plant to another while holding constant power delivered to all loads and generation at all other plants, as developed by W. R. Brownlee.[4] The same principles apply when generation is increased at one plant to supply an increment increase of a single load plus the related increment increase in losses while holding constant power delivered to all other loads and generation at all other plants.

Equation 13 of reference 4, which gives the incremental loss associated with transferring power from point 1 to point 2 on the system by the 2-step method, expressed in terms of sending-end power is

$$\frac{dL}{dP_{1-2}}=\frac{4K\tan 1/2\theta_{1-2}}{(K+\tan 1/2\theta_{1-2})^2} \qquad (5)$$

In reference 4 it is shown that the incremental loss given by equation 5 is independent of the magnitude of the transfer impedance between points 1 and 2, of the relative and absolute magnitude of the bus voltages at the two points, and of the reactive/real power ratio of the generating plant.

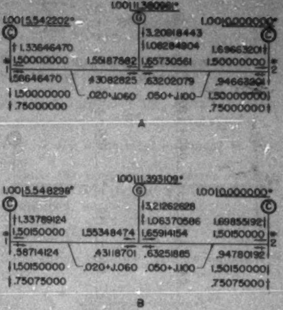

Fig. 1. System used for illustrating $(\Delta L)/(\Delta P)$ method of calculating actual incremental loss

Equation 5 can be expressed in another form which has been found more convenient for making computations

$$\frac{dP_L}{dP_{m\rightarrow n}}=1-\left(\frac{K_{mn}-\tan 1/2\theta_{mn}}{K_{mn}+\tan 1/2\theta_{mn}}\right)^2 \qquad (6)$$

where

$\frac{dP_L}{dP_{m\rightarrow n}}=(dL)/(dP_{1-2})$ of equation 5 and represents the incremental loss incurred in transferring power from source m to load n, under the conditions stated in the foregoing, expressed in terms of sending-end power

θ_{mn} = angle by which the bus voltage at the sending end m leads the bus voltage at the receiving end n

K_{mn} = reactance-resistance ratio of the transfer impedance between points m and n

When the incremental loss given by equation 6 is expressed in terms of power received at n it becomes

$$\frac{dP_L}{dP_{m\leftarrow n}}=\left(\frac{K_{mn}+\tan 1/2\theta_{mn}}{K_{mn}-\tan 1/2\theta_{mn}}\right)^2-1 \qquad (7)$$

The incremental loss from a source to the composite system load (partial derivative of losses with respect to the source) can be expressed as the summation of the incremental losses incurred in transmitting power from the source m to each of the loads n, expressed in terms of power received, divided by 1 plus the said summation of the incremental losses incurred in transmitting power from source m to each of the system loads n. In this expression, unity represents the incremental increase in power received at all loads. The per-unit incremental loss incurred in transmitting an increment of power to each of the individual loads

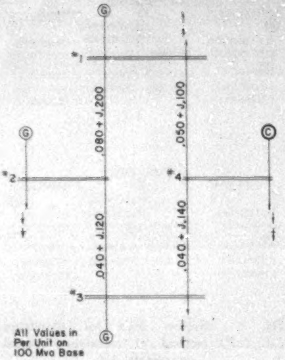

Fig. 2. Impedance diagram

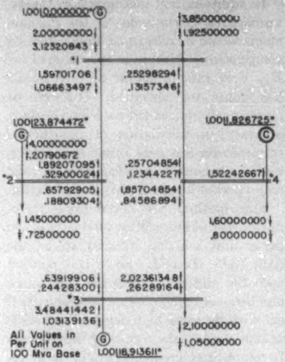

Fig. 3. Case B-1 load flow

should be represented by the incremental loss in transmitting power from source m to load n times the ratio that the incremental increase in each load n bears to the incremental increase in the total load $(dL_n)/(dL_T)$. This can be expressed in equation form

$$\frac{\partial P_L}{\partial P_m}=\frac{\sum_n \frac{dL_n}{dL_T}\,\frac{dP_L}{dP_{n\leftarrow m}}}{1+\sum_n \frac{dL_n}{dL_T}\,\frac{dP_L}{dP_{n\leftarrow m}}} \qquad (8)$$

where

$\frac{\partial P_L}{\partial P_m}$ = incremental loss of source m

$\frac{dL_n}{dL_T}$ = ratio of incremental increase of load n to incremental increase of total load

A rigorous derivation of equation 8 is given in the Appendix.

Application of Method

Some discussers[5] have criticised Mr. Brownlee's voltage phase-angle method of determining increment loss,[4] claiming that it would break down under certain combinations of phase angles, different reactance-resistance ratios in the various lines of the system, loads located on a line connecting two generating plants, and a generating plant located on a line connecting two other generating plants and having a phase angle substantially greater or less than the phase angle of the two end plants. Although Mr. Brownlee in his closure appears to have satisfactorily answered the questions raised by these discussers, it is desirable that the accuracy of the method presented in this paper for determining the value of the general loss equation constants be tested under adverse conditions and, to do this, the adverse factors referred to in reference 6 have been incorporated in the system used to illustrate the application of this method. The system selected, shown in Fig. 2, is a 3-source 4-load loop system having different reactance-resistance ratios for each transmission line, with a load located on a line connecting two generating plants and a generating plant located on a line connecting two other generating plants. In some of the cases studied, the voltage phase angle of the intermediate plant is considerably greater than that of the two end plants; in other cases studied it is considerably less.

For illustration, the value of the general loss equation constants will be determined for the system shown in Fig. 2, and incremental loss and total loss values will be computed using the general loss equation and compared with actual loss values and actual I^2R losses for a number of cases representing typical distribution of power supply by sources for peak period, median, and valley period load conditions. Load distribution for the three load periods is shown in Table II.

It will be noted that each of the loads varies at a different rate and do not remain a constant fraction of the total system load. Also, the difference in the ratio of valley load to peak load is representative of that normally found between substations serving different types of loads on a typical power system. The distribution of the change in total system load by loads is also shown in Table II.

Six representative cases of power supply by sources, three for peak period loads, and three for valley period loads, will be used in determining the loss equation constants. Power supply by sources, I^2R loss, and incremental loss of each source computed by equation 8 are shown in Table III. Fig. 3 shows the load-flow diagram for case B-1. Solution of the ten simultaneous equations for incremental loss and I^2R loss, based upon the data of Table III, gives the values for the general loss equation constants, shown in Table IV.

The assumptions on which the general loss equation is based are:

1. The variation in each substation load is a fixed percentage of the variation in system total load. This percentage is not related to the size of the load. For example, no problem is presented by a large load of 100-per-cent load factor, in which case the load variation would be zero per cent of the system total load.
2. The reactive power generation is that required to maintain the peak period and valley period bus voltage levels established in the cases studied on the network analyzer to obtain the data used in setting up the simultaneous equations for determining the loss equation constants.

Table II. Load Distribution for Three Load Periods and Distribution of Change in Total System Load

Comparison of Results

A comparison of incremental loss and total system loss, given by equations 2 and 3, with actual system I^2R loss and actual incremental loss values, as determined by the $(\Delta L)/(\Delta P)$ method, is given in Table V. The 15 cases shown cover a wide range of system conditions. Peak period, median, and valley period loads are represented, and power supplied by each source covers the full range from minimum to maximum output. System I^2R losses range from a minimum of 0.9 per cent to a maximum of 11.6 per cent, and incremental loss values vary from −25 per cent to +35 per cent. The difference in bus voltage phase angle between power supply sources runs as high as 45 degrees.

The close agreement of actual values of incremental loss and total system loss with those computed by the general loss equation, as shown in Table V, fully supports the principles on which the general loss equation is based and the method of determining the equation constants. The system used to illustrate this method incorporates all of the adverse factors which the critics of the voltage phase-angle method claimed would cause this method to fail. Even better results can be expected when the general loss equation is applied to a system in which such adverse factors are not predominant. The procedure outlined by Mr. Brownlee in his closure of reference 4 for applying this method to line systems should be followed.

Conclusions

A new type of general loss equation has been developed which has the following distinctive characteristics and advantages:

1. Proper recognition is given to the effect that the difference in distribution of load by substations for maximum and minimum load conditions has upon both total system loss and incremental loss of the various power supply sources.

2. The important effect that the rate at which each substation load is changing has upon incremental loss values is recognized and taken into account in determining such values.

3. Reactive-power generation and flow is that required to maintain the system schedule of bus voltage levels during both peak and valley periods.

4. There is no restriction upon the maximum bus voltage phase angle between power supply sources, which makes the general loss equation especially applicable to interconnected systems where such angles across the system may be large.

5. It is not necessary to treat large nonconforming loads as sources of negative power supply, provided the daily variation in the nonconforming loads is followed consistently.

Appendix. Derivation of Equation 8

Consider the sum of contributions to the system transmission loss dP_L arising from increments of power $dP_{n\leftarrow m}$ received at each load from plant m as load changes $dL_n = dP_{n\leftarrow m}$ occur. The individual loads in general have different rates of change with respect to the total load.

With all other loads and sources being held constant, the total change in system loss is

$$dP_L=\sum_n \frac{dP_L}{dP_{n\leftarrow m}}(dP_{n\leftarrow m}) \tag{9}$$

With all other sources held constant, the total change in input power is

$$dP_m=dL_T+dP_L=\sum_n dL_n+dP_L \tag{10}$$

since $\Sigma\ dL_n$ is the total increment in load dL_T.

Since the increment in power received from source m at the load n is the increment in the load

$$dP_{n\leftarrow m}=dL_n \tag{11}$$

Substituting equation 11 into equation 9 gives

$$dP_L=\sum_n \frac{dP_L}{dP_{n\leftarrow m}}(dL_n) \tag{12}$$

Substituting equation 12 into equation 10 gives

$$dP_m=dL_T+\sum_n \frac{dP_L}{dP_{n\leftarrow m}}(dL_n) \tag{13}$$

Dividing equation 12 by equation 13 and then dividing numerator and denominator by dL_T gives

$$\frac{dP_L}{dP_m}=\frac{\partial P_L}{\partial P_m}=\frac{\sum_n \dfrac{dP_L}{dP_{n\leftarrow m}}\dfrac{dL_n}{dL_T}}{1+\sum_n \dfrac{dP_L}{dP_{n\leftarrow m}}\dfrac{dL_n}{dL_T}} \tag{14}$$

when all other sources are held constant.

Discussion

W. R. Brownlee (Southern Services, Inc., Birmingham, Ala.): This paper presents a significant forward step in the development and verification of practical methods for the computation of incremental transmission losses as functions of generator powers. Of far-reaching importance is the new method for deriving constants which will take into account a different rate of change for each individual load on the system. Previous analyses have recommended setting up negative generators to represent loads which have different rates of change. Such an expedient is practical for a very limited number of loads and at the expense of using up valuable space in the generation matrix. The beneficial influence of the new method is apparent in Table V, where excellent performance of the constants is obtained over a wide range of generation. It is believed difficult to find a practical interconnected power system with loads of such a uniform rate of change that this factor can be ignored safely. A comparison of results using the simplified loss formula applied to the system studied by the authors would be of interest.

The method used to demonstrate incremental losses, employing very small increments of power and carrying the computation to many significant figures, is most interesting. It is believed to be the first published correlation of arithmetic incrementals with system loss constants and provides further confirmation of the adequacy of the phase-angle method. Previous analyses have employed substantial exchanges of generation and comparisons of the resulting total losses, but it has been demonstrated that a total loss comparison can conceal serious errors in the incremental loss determinations.[1]

Table VI. Values Using New Constants and Phase Angles

	From New Constants, Per Cent	From Phase Angles, Per Cent
dL/dP_{21}	27.8	27.9
dL/dP_{23}	7.9	5.8
dL/dP_{31}	21.5	22.1

The question may well arise as to whether this new loss formula, making use of different rates of change of system loads, would therefore distort the indicated incremental loss between pairs of plants for a particular system load. That is, the loads would not change at all when the generation of one plant is increased and that of a second plant reduced by the proper amount. This characteristic of the new loss formula may be tested by calculating the incremental loss between a pair of plants from the values derived by the authors for incremental losses between each plant and the load, making use of equation 16 of a previous paper.[1] These values may then be compared with those obtained from phase-angle functions. Table VI shows satisfactory conformance between the values using the new constants and the direct phase-angle quantities.

One disadvantage of this new method is the relatively high cost of solving the simultaneous equations, although such cost is justifiable if no adequate method is available at a lower cost. Experience must determine if the limitations of network analyzer technique may complicate the accurate solution of the simultaneous equations.

The concept of incremental losses existing between plants with zero generation at all of them provides an excellent physical picture of the meaning of the added terms in the loss formula. In this connection, it is noted that the simultaneous equations determine all of the constant including B_{n0} and K_{L0}. It may be feasible to calculate these additional constants directly on a network analyzer. At zero power supply, system generators would be represented by adjustable capacitors for holding voltage, and approximately half of the loads would be represented by board generators. This would require a large analyzer with, say, 30 generators or the use of divider circuits.

This new method has much to commend it. It makes no use of a grounded reference point, does not need a w' factor, and requires no separate consideration of the elusive Q/P ratios required with certain previous methods.[2] Emphasis is on incremental losses, and the basic assumptions are compatible with actual power system practices.

Charles R. Cahn (Syracuse University, Syracuse, N. Y.): This paper provides an interesting new approach to the evaluation of total loss formula coefficients using data from a number of load studies over a wide range of system conditions rather than from a single base case study. Although the method of the paper utilizes Brownlee's expression for the incremental loss, which is justified for systems on which the X/R ratios of the transmission lines are reasonably the same, the $\Delta L/\Delta P$ method could be applied instead if an automatic digital computer is used to obtain the necessary load flows.

The most obvious objection to the proposed method is the enormous amount of computations necessary to set up and solve the simultaneous equations for the unknown loss formula coefficients. However, since the loss formula is used in system operation only to provide incremental losses, I made an investigation of the possibility of directly finding incremental loss formula coefficients instead. The most general linear expression for the incremental loss resulting from an incremental exchange of generation at constant system load between source n and a selected source M is

$$dP_L/dP_n=\sum_{m=1}^{N}A_{nm}P_m+A_{n0} \tag{15}$$

where P_m is the power input to the system from source m, the A's are constants, and N is the total number of sources. There are $N+1$ coefficients to be found for each value of $n\neq M$. Values of dP_L/dP_n from $N+1$ different load studies, obtained either by Brownlee's method or by the $\Delta L/\Delta P$ method, allow simultaneous solution for the A coefficients.

The same $N+1$ load studies also allow solution for the coefficients in equation 15 for the other values of n. The matrix that has to be inverted is the same for all values of n and is only of the $N+1$ order. Of course, a least square fit to more than $N+1$ load studies is permissible.

For a system with more than four generators the incremental loss formula has a greater number of different coefficients than does the total loss formula and should therefore be more accurate, although the total loss formula has the advantage of being fitted to both total and incremental losses.

The method just described was applied to the example in the paper for purposes of comparison, using the data from Table III for the same six cases. Generator three was chosen as the swing generator ($M=3$). It was necessary to calculate from the given data the incremental loss associated with exchanging generation at constant system load between source one or two and source three. The pertinent equation is

$$dP_L/dP_n=\frac{\partial P_L/\partial P_n-\partial P_L/\partial P_3}{1-\partial P_L/\partial P_3} \tag{16}$$

as shown in reference four of the paper. Only the results for an exchange of generation between sources one and three are

Table VII. Comparison of Actual and Calculated Incremental Losses. dP_L/dP_1 Is in Per Unit

*Calculated from Table V by equation 16.

included here. The incremental loss formula which best fits cases A-1, A-2, A-3, C-1, C-2, and C-3 is

$$dP_L/dP_1 = 0.07096P_1 - 0.03098P_2 - 0.07629P_3 - 0.07778 \quad (17)$$

In addition, an incremental loss formula was calculated from the B-1 load study, using slopes of the generator power-reactive characteristics at the median load level, by a direct method.[1] A constant term was added to give the best fit with the given six cases. The resulting equation is

$$\frac{dP_L/dP_1}{1-\frac{1}{2}dP_L/dP_1} = 0.0685P_1 - 0.0239P_2 - 0.0660P_3 - 0.0731 \quad (18)$$

A comparison of the various equations is given in Table VII. It is seen that the total loss formula of the paper is most accurate, presumably because of its larger number of coefficients with a small 3-source system. Interestingly, the incremental loss formula of equation 18, which is much more easily obtained than that of equation 17, also appears to be the more accurate of the two incremental loss formulas.

These results indicate the possibility of greatly simplifying the method of the paper without altering the basic approach to the problem. The possibility of including the effects of loads varying at different rates in a direct method of evaluation with an additional reduction in complexity is also shown.

REFERENCE

1. THE DETERMINATION OF INCREMENTAL AND TOTAL LOSS FORMULAS FROM FUNCTIONS OF VOLTAGE PHASE ANGLES, C. R. Cahn. *AIEE Transactions*, vol. 74, pt. III, Apr. 1955, pp. 161–76.

J. B. Ward and **H. W. Hale** (Purdue University, Lafayette, Ind.): The authors are to be complimented on a very good paper. Of particular interest is the method presented for the empirical evaluation of loss formula coefficients. We would like to comment on several statements made by the authors and on several aspects of the theory and methods presented in the paper.

Reference is made to the four basic assumptions of the so-called "simplified" loss equation and to the elimination of these assumptions by the method of the paper. Of course, examination reveals that the assumptions have been relaxed or reduced to some extent, and some of the original assumptions referred to are replaced by new ones, but to the casual reader the statement might imply that all assumptions are removed. Hence the nature of assumptions and approximations might be clarified. We would be interested in having the authors summarize assumptions relating to loads, source bus voltages, source bus angles, and source power factors which are involved in applying their loss equation to a system operating condition which deviates widely from any of the conditions utilized in evaluating the constants.

We wish to supplement the authors' presentation of an empirical method with a brief discussion of how the former loss formula methods can be generalized in form and how the four assumptions previously referred to can be relaxed to some extent.

Considerable emphasis in the paper is placed on the effect of rate of load change on incremental loss values. Implied in the authors' discussion of this matter is a particular definition of incremental loss associated with a certain plant: namely, the incremental loss of plant 1, e.g., is associated with an increment change in output of that plant alone with other plant outputs constant, the increment increase arising from an increase in total load in which all loads individually share the increase in accordance with specified constant rates of change. We would like to point out that for the purpose of achieving economic dispatch of generation the actual rate of change of system loads with respect to either total load or time is not essential. An incremental loss for each plant can be defined in terms of a variation of any one load or group of loads, independently of how total load variation is shared by the individual loads.[1,2]

The form of loss formula containing the first-degree terms and a constant is certainly more versatile than the form containing second-degree terms only. This general form arises naturally from mathematical considerations. Consider a power system with n sources and with load characteristics completely defined. The total loss may be viewed as some complicated function of n variables, namely the plant loadings. Under certain restrictions, such a function can be expanded in the form of a Taylor's series. One form of Taylor's series for a function of n-variables is shown in equation 19. Here the P's are the variables, and the coefficients

$$L(P_1,P_2,\ldots P_n) = A_0 + \sum_i A_i P_i + \sum_i \sum_j A_{ij} P_i P_j + \sum_i \sum_j \sum_k A_{ijk} P_i P_j P_k + \ldots \quad (19)$$

are combinations of various partial derivatives of the function evaluated at the origin or at some other point. Fourth and higher order terms would appear, but are omitted here. We see that the third term alone is the familiar form of loss formula, and a more accurate approximation will be obtained the more terms that are used. This is not presented as a possible method of deriving a loss formula, because the function must be known in order to take the derivatives required for writing out the coefficients; however, there may be some profit in visualizing the problem from this viewpoint and in studying the nature of the Taylor's series coefficients.

A loss formula including first-degree terms and a constant can be derived from the original loss formula. This can be done and at the same time the assumptions referred to by the authors can be relaxed to some extent without the necessity of an entirely different method. This will be presented in brief outline, without detailed steps necessary for practical accomplishment.

$$L = \sum_m \sum_n B_{mn} P_m P_n \quad (20)$$

$$L = P_1^2 B_{11} + P_2^2 B_{22} + [P_r^2 B_{rr}] + 2P_1 P_2 B_{12} + 2P_1 P_r B_{1r} + [2P_2 P_r B_{2r}] \quad (21)$$

$$\frac{\partial L}{\partial P_1} = 2P_1 B_{11} + 2P_2 B_{12} + [2P_r B_{1r}] \quad (22)$$

$$P_r = a(P_1 + P_2) + b \quad (23)$$

$$\frac{\partial L}{\partial P_1} = 2P_1 B_{11}' + 2P_2 B_{12}' + B_{10} \quad (24)$$

Consider, e.g., a system consisting of two plants and two groups of loads of different characteristics. Equation 20 shows the so-called simplified loss equation for n sources. Let us apply this equation, treating one load group as the loads in the usual way and treating the other load group P_r as an additional source. Expanded, this yields the loss formula shown in equation 21. Here the contribution of load group P_r is given by the terms within brackets. Observe that for a given P_r this contribution takes the form of a constant term and first-degree terms in P_1 and P_2. In this equation, relationship between the two load groups is not restricted to a linear one.

Equation 22 is the incremental loss associated with plant 1 as obtained by differentiating equation 21 with respect to P_1. For a given value of P_r, the last term is a constant. Let us examine the meaning of equation 22. Differentiation of equation 21 in this way implies that plant 2 output is constant and load P_r is constant. Thus the increment in loss is associated with an increase in one load group alone, with this increase being picked up on plant 1 alone. Differentiation of equation 21 with respect to plant 2 has a similar interpretation, and the resulting incremental loss values are perfectly valid in applying the established criterion for determining optimum dispatch of generation.

This form of incremental loss equation might be entirely practical to use in conjunction with an optimum dispatch computer. The P's are variables and terms associated with different load groups can be treated as parameters. It is necessary to set these parameters in accordance with the values of the loads at a given time, but rates of change of the loads are not necessary. Curve followers or some other means could control equipment simulating these parameters in accordance with any complicated load curves.

Next, let us impose a constraint on the variation of the load P_r. Specifically, assume that this load group varies in a linear fashion with the total generation as indicated in equation 23. This is approximately the same specification of load characteristics as proposed in the paper, except that there the individual load or load group is assumed to be a linear function of the total load instead of generation. Either representation will probably serve equally well as an approximation of actual load characteristics, which are of course much more complicated than the proposed straight-line relationships. If equation 23 is substituted into 21, and terms collected, a total loss formula is obtained which has quadratic terms, first-degree terms, and a constant. Differentiation with respect to P_1 will yield equation 24. Here the significance of the partial derivative is the same as that in the paper, namely, an increase in total load is shared by all loads in a specified (linear) way, and the resulting increment in loss is assigned to the one plant which picks up the increase.

We would expect that such a method of expanding the original form of loss formula to take care of various load groups would

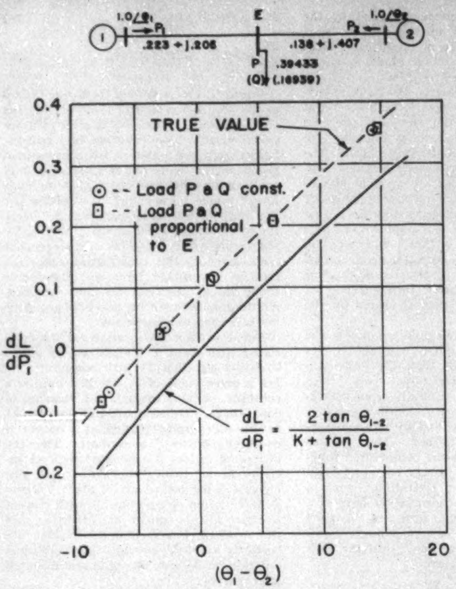

Fig. 4. Curves for incremental loss

yield adequate accuracy for many practical systems, and it might have some distinct advantages over the empirical determination of the coefficients. In the event that seasonal changes, or strikes, or some unforeseen contingency should alter the relationships between variations of the different load groups, it would not be necessary to start from the beginning and derive a new loss formula. New linear relations, such as equation 23, could be imposed and a rather minor portion of the computations repeated to obtain the new coefficients.

Finally, we would like to comment on the reference by the authors to the closure of Brownlee's recent paper.[3] In that paper, several discussions pointed out approximations inherent in Brownlee's method which were not explained in the paper. Specifically, it was pointed out that effects of the nonuniform R/X ratio and the presence of intermediate loads along lines connecting plants can introduce serious error in application of the proposed methods. In the closure referred to, the author argued that actual power system loads vary nearly as the first power of voltage and then he dispatched the related discussions very briefly with the statement: "Accordingly the load current does not change with voltage variations produced by normal exchanges of generation between sources, and thus cannot alter the incremental losses between plants." We believe this statement is not correct, and to illustrate, consider the system shown in Fig. 4. Here, two plants supply power to a single intermediate load. The two line sections exhibit a modest nonuniformity of R/X ratio. The application of the phase-angle formula for incremental loss associated with transfer of power between plants gives the solid line. The true incremental loss is given by the dotted line and, as indicated in the figure, representation of the load as power and reactive varying with the first power of voltage gives almost exactly the same true incremental loss characteristic as does constant power load. The points on the true curve were obtained by a digital solution of the system carried out to eight decimal places, and by using very small increments so that rate of change of loss is correct to three figures. The effect of intermediate loads can be an important factor, and needs further study and evaluation. The approximations of this sort which are inherent in the phase-angle method appear also in empirical evaluation of coefficients by methods of the present paper. It is shown in the paper that the methods can succeed very well in producing an accurate incremental loss formula; however, success in a single example where adverse conditions are present is of little value in discounting the potential hazards of these approximations. In the absence of complete theoretical evaluation of the assumptions, empirical evaluation requires a large amount of data.

3. See reference 4 of the paper.

E. D. Early, R. E. Watson, and G. L. Smith: We appreciate the valuable contributions of the discussers. We note that the improved accuracy offered by the expanded form of the general loss equation presented in the paper was accepted by all the discussers, critical comment being limited to the method of determining the coefficients of the equation.

Mr. Brownlee and Mr. Cahn refer to the relatively high cost of solving the simultaneous equations, although Mr. Brownlee points out that the improved accuracy fully justifies the increased cost. Fortunately there is a much simpler method of solving the simultaneous equations at a cost that is a small fraction of $1,500 to $2,000. This method was not presented in the paper because it is not rigorous, although the results are just as accurate as those given by the rigorous method.

Equation 2 of the paper is repeated here and equation 25 is a rearrangement of equation 4

$$\sum_m 2B_{nm}P_m + B_{n0} = \frac{\partial P_L}{\partial P_n} \qquad (2)$$

$$\sum_n B_{n0}P_n + K_{L0} = L - \sum_n {}^1/_2\left(\frac{\partial P_L}{\partial P_n} - B_{n0}\right)P_n = L - P_n\sum_m B_{nm}P_m \qquad (25)$$

Comparison of equations 2 and 25 shows the left-hand side of the two equations to be identical except for the coefficients. Therefore the solution of one equation is the solution of the other when expressed in terms of a general answer. This type of general solution is equivalent to inverting the matrix in the matrix algebra solution. These equations have only $(n+1)$ unknowns and require only $(n+1)$ simultaneous equations for solution. Instead of solving 105 simultaneous equations for a 13-source system, it is necessary to solve only one set of 14 simultaneous equations in terms of a general answer, or to invert a 14 square matrix. Since the cost of solving simultaneous equations varies as the square of the number of terms, the cost of solving 14 simultaneous equations is less than one-fiftieth the cost of solving 105 simultaneous equations.

Substituting values of incremental losses for each source given by equation 8 in the general solution of equation 2 gives values for all B_{nm} and B_{n0} constants. Two values of each mutual constant will be obtained and B_{mn} may not be equal to B_{nm}, although the two values will usually be in close agreement and it is believed that they would be identical if the incremental loss values substituted were absolutely accurate.

The two values obtained for each B_{mn}-B_{nm} constant are averaged to obtain a single value for each of the mutual constants. The values of the terms $P_n\sum_m B_{nm}P_m$ are then computed and substituted in the general solution of equation 25 which gives the values of the B_{n0} and K_{L0} constants. It should be noted that in this procedure the B_{n0} values determined from the incremental loss equations are discarded and those determined by the total loss equation used in the final solution, the B_{n0} constants having a greater effect upon total losses than upon incremental losses, as stated in the paper.

Table VIII shows a comparison of the general loss equation constants given by the rigorous and nonrigorous methods and Table IX shows a comparison of incremental and total loss values given by the general loss equation with its constants determined by the rigorous and nonrigorous methods. The values obtained using the two methods are practically identical, and the values of incremental and total system losses given by the nonrigorous solution have the same high degree of accuracy as those given by the rigorous solution.

Mr. Ward and Mr. Hale request that assumptions relating to loads, source bus voltages, source bus angles, and source power factors involved in the general transmission loss equation be summarized. They are as follows:

1. The load of each substation for system peak load and minimum load conditions is determined and the assumption is made that each substation load varies between its peak load and minimum load values linearly with total system load. This assumption results in actual load distribution at system peak load and minimum load, the distribution for intermediate system loads being in error to the extent that the relationship between the variation from maximum to minimum for all loads is not linear. This assumption is considerably more accurate than the assumption that all loads remain a constant fraction of the total system load, which assumption is valid for the base load condition only.

2. Actual source bus voltages are established for both system peak load and minimum load conditions and the assumption is made that each bus voltage varies linearly with total system load from its value at peak load to its value at minimum load. This assumption is more realistic than the assumption that source bus voltages remain constant at their base load value for all other system loads.

3. No assumptions are made with regard to source voltage phase angles. In conventional methods of determining the coefficients of the simplified loss equation, source voltage phase angles are assumed to be held constant.

4. Actual load power factors, including the effect of fixed and switched capacitors, are established for each load for both system peak load and minimum load conditions and it is assumed that the power factor of each load varies from its value at system peak load to its value at minimum load linearly with total system load.

5. No assumptions are made regarding source power factors, the reactive generation at each source being that required to supply the load and maintain source bus voltages. In other methods, the ratio of reactive to real power generation (Q/P ratio) is assumed to remain at a fixed value. Recently this assumption has been relaxed somewhat by holding constant a part of the reactive generation and assuming that the remainder varies linearly with real power generation.

It will be noted that many of the assumptions of the conventional method of determining the value of the coefficients of the simplified loss equation have been eliminated entirely while others have been replaced with new assumptions that are more realistic.

Mr. Ward and Mr. Hale call attention to the fact that loads which do not vary linearly with total system load can be treated as a source of negative power supply if such loads are telemetered or can be determined with the necessary degree of accuracy by curve followers or otherwise. This is a well-known principle and three large nonconforming loads are so treated in the computer for incremental cost of delivered power described in a companion paper.[1] We do not agree that all loads can be divided into two or more groups and treated in this manner since to do so would eliminate the change in losses that would occur within the group as generation is shifted between plants and as the total load or distribution of load by groups change. Since it is necessary to represent separately each load used in the network analyzer study and since the loads not supplied directly from a generating plant bus are usually larger in number than the power supply sources, the number of loss equation constants to be determined would be increased four or more times if each load were treated as a source of negative power supply. Treating each load as a source of negative generation may be more accurate but, since the number of loss equation constants and the corresponding computer components are increased several times, use of the method does not appear to be economically feasible.

We do not agree that the method used by Mr. Ward and Mr. Hale to develop the coefficients of the general loss equation from the simplified loss equation is correct, because no consideration is given to the effect of the fixed total system loss (K_{L0}), and because individual loads are assumed to vary as a linear function of total generation rather than as a linear function of total system load. The inaccuracy of this assumption will be recognized readily when it is remembered that, for a fixed total system load, total generation and system losses can vary over a wide range as generation is shifted between generating plants. If loads are assumed to be a fixed fraction of total generation, the total system load would increase or decrease in direct proportion to total system generation and losses would remain a fixed percentage of total system generation which is incorrect.

If the correct assumption that individual loads vary as a linear function of total system load is made, namely

$$P_r = a(P_1+P_2-L)+b \tag{26}$$

$$P_S = c(P_1+P_2-L)+c \tag{27}$$

and equations 26 and 27 are substituted for P_r and P_S in equation 22, the resulting coefficients of the general loss equation will be complicated second-degree functions of

P_1 and P_2 and not constants, the resulting equations being so complex that evaluation by either digital or analogue computers is impractical.

It was stated in the paper that not less than $(n+2)$ cases are required to be studied on the network analyzer, where n is the number of sources, and Mr. Ward and Mr. Hale stress the importance of obtaining a large amount of data to insure accurate determination of the loss equation coefficients by the empirical method of the paper. On the other hand, it is the large amount of data used which insures the accuracy of the results obtained. When the loss equation is tied into (n^2+2n) incremental loss values and $(n+2)$ I^2R loss values covering a wide range of distribution of generation by sources for both peak and valley loads, values computed from the loss equation involve a process of interpolation between a large number of known limits and cannot be seriously in error when the values used for the limiting cases are correct.

The conventional method of determining coefficients of the simplified loss equation ties into I^2R losses for the base case only and values computed from this equation involve a process of extrapolation beyond known limits, a process subject to unlimited error unless the determination of the coefficients for the base case is based entirely upon sound theoretical principles. Although the methods used in determining these constants are considered to be based upon sound theoretical principles, so many unrealistic assumptions are made that it is necessary to introduce an empirical process in evaluating the w' or R_{LL} factor in order to force the loss equation to give correct I^2R losses for the base case, and the Q/P factor is determined entirely by empirical considerations.

The phase-angle method is used for determining incremental loss values because it is the only practical method available for determining these values from network analyzer data. Tying in with I^2R losses for each of $(n+2)$ cases offsets to a large extent any inaccuracies in the incremental loss values given by the phase-angle method. For example, in case A-2 the incremental loss values given by the phase-angle method, Table III, are completely reversed from the actual values but the values computed from the loss equation, Table V, are in close agreement with actual values.

Mr. Ward and Mr. Hale also present a discussion of the closure of a previous paper[2] designed to show that the Brownlee phase-angle method is inaccurate when used to determine incremental loss associated with the transfer of power from one source to another source, with the load held constant, over a line type system consisting of two generating plants feeding a single load over separate lines having different X/R ratios, one of which is less than unity and corresponds approximately to no. 3 copper, a conductor size not normally used on utility transmission systems.

The discussion does not appear to be applicable to the subject paper since this paper uses the phase-angle method to determine the incremental loss associated with transferring power from a source to a load while holding all other source and load powers constant. The system of the paper is a loop system with the X/R ratio of the lines varying over wide limits and with a load located between two sources. The accuracy of the results obtained, shown in Table V, speaks for the accuracy of the methods employed.

We would like to point out that the X/R ratio of the transfer impedance between sources and loads is usually limited to a small range on typical utility systems although the range of the X/R ratios of the separate lines may be large. For example, on a large utility system covering 100,000 square miles the X/R ratio of the separate lines ranges from 1.4 to 6.5 but 98 per cent of the transfer impedance X/R ratios fall in the limited range from 1.9 to 2.6 inclusive.

Mr. Cahn recognized that an independent set of equations representing incremental loss values could be set up for each source and solved to determine the B_{mn} constants. His method is similar to the nonrigorous solution presented in this closure but differs in that the solution is not tied in with system I^2R losses, which accounts to a large extent for the failure of Mr. Cahn's equation (17) to give results that are as accurate as those given by the general loss equation of the paper.

Equation 18 gives better results than equation 17, probably because I^2R losses are included in the derivation of this equation but are less accurate than those given by the general loss equation of the paper in 10 out of 15 cases. Both equations 17 and 18 represent incremental losses incurred in transferring power from one source to another at constant system load and not from a source to the load, and since this relationship is nonlinear, as shown by equation 16, it cannot be accurately represented by a linear equation such as equation 17 or 18.

Table X shows a comparison of actual and computed incremental and total loss values given by the simplified loss equation for the system of the paper, as requested by Mr. Brownlee. It will be noted that both incremental and total loss values given by the simplified loss equation are considerably less accurate than those given by the general loss equation of the paper, shown in Table V, the error in computed values being of such magnitude as to materially affect economy loading of units. Attention is directed to the fact that total losses given by the simplified loss equation are in general higher than the actual I^2R losses for peak period loads and lower than actual I^2R losses for valley period loads, which results from the inability of the simplified loss equation to take into account the shift in the system load center between peak and valley load periods when each of the loads vary at different ratios.

In applying the simplified loss equation the most recent improvements in determining the B constants were used, such as including out-of-phase components of load currents and excluding the fixed portion of Q that does not vary with generation in determining the Q/P ratio for each source.[3]

Transient Durability Testing of Valve Type Lightning Arresters

J. W. KALB
MEMBER AIEE

A. G. YOST
ASSOCIATE MEMBER AIEE

THE DESIGN testing of the valve type of lightning arresters is difficult, if for no other reason than that there is such an enormous range of performance factors which must be investigated. A lightning arrester must fulfill the following requirements:

1. Normally function as an insulator, withstanding normal system line-to-ground voltage.
2. Discharge, without damage to itself or associated equipment, transient disturbances ranging from less than 100 to many thousand amperes, and from a few microseconds' duration to several milliseconds' duration.
3. Operate as a circuit interrupter to stop the flow of power frequency follow current subsequent to unit operation resulting from transient disturbances.

Increasing the problem are the difficulties associated with obtaining substantial statistical information concerning the durations and wave shapes of surges discharged by lightning arresters. The equipment necessary to measure characteristics other than crest magnitude[1-5] is so costly as to preclude widespread installation.

Standard lightning arrester tests[6,7] are, of practical necessity, inadequate to explore all aspects of field performance. However, they are subject to reasonable duplication among different laboratories, and they form a basis of comparing relative lightning-arrester performance.

This paper describes some additional tests, as well, as alterations of standard tests, made in an effort to explore field performance characteristics. These tests are not suggested as revisions of the standard tests. In general, they involve testing techniques or possible interaction of circuit components to a degree which would render duplication among different laboratories most difficult.

Apparatus Tested

All tests were performed on standard production lightning-arrester units manufactured by the authors' company. Two types were tested. Type *GP* is designed for general-purpose station use in voltage ratings of 3 through 121 kv. Type *MP*, also designed for station use, offers better protective characteristics and greater durability than type *GP*. Type-*MP* voltage ratings are 3 through 276 kv.

Fig. 1 shows the active valve and gap elements from 4.5-kv units of these designs. The type-*MP* gap uses a separate arc-interrupting chamber to obtain more positive follow-current interrupting ability than is possible with the conventional multigap design of type-*GP* gap elements.

Circuit Voltage Drop

To accommodate power frequency test equipment of limited kva rating, the standard operating duty cycle tests permit a measurable reduction beneath open-circuit test voltage during follow-current flow. The AIEE standard[6] permits a voltage drop of not more than 10 per cent(%) of open-circuit voltage. The National Electrical Manufacturers Association standard[7] requires that the test be made using a power source of 500- to 1,000-ampere rms fault current (the current which would be obtained if the line and ground terminals of the test piece were bolted together). These test circuits result in a power circuit test condition less severe than service conditions may be because of the following conditions:

1. Follow current may be substantially less than it would be with full-rated voltage across the lightning arrester—a condition possible at high fault current locations. This reduced follow current in the test circuit results in less current-interrupting duty on the gap element and less voltage stress on the valve element.
2. The test circuit reactance, while permitting a substantial reduction in power follow current, is insufficient to result in a more severe recovery voltage transient across the gap element.

The left-hand oscillogram of Fig. 2 shows voltage and current during a standard unit operation with 10-kiloampere, 12x45-microsecond impulse on a type-*MP* lightning arrester of 4.5-kv rating. This impulse, discharged through the lightning arrester at the time indicated by the arrow, initiated the 230-ampere follow-current loop shown in the upper trace. Test circuit fault current was 1,000-ampere rms. Open-circuit test voltage was 4.5-kv rms (6.36-kv crest), and the voltage drop during follow-current flow was 6.5%.

The right-hand oscillogram of Fig. 2 was obtained with the same lightning arrester, but with open-circuit voltage increased until voltage (6.36-kv crest) during follow-current flow was equal to the lightning-arrester rating. This increased the follow-current from 230 to 295 amperes.

This 28% increase in follow current with rated voltage maintained across the test piece is evidence of the limitations inherent in the standard tests as a criterion of design adequacy. Since the 60-cycle voltage rating of the lightning arrester is a maximum value which the arrester may have to meet in service, it is necessary for the design engineer to conduct some duty cycle tests with at least full-rated voltage across the arrester

Paper 55-136, recommended by the AIEE Protective Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 18, 1954; made available for printing November 29, 1954.

J. W. Kalb and A. G. Yost are with the Ohio Brass Company, Barberton, Ohio.

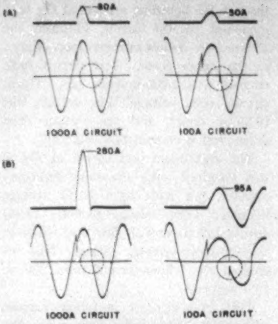

Fig. 3. A—Oscillograms showing satisfactory unit operations with type-GP lightning arrester in a 1,000-ampere fault current circuit and in a 100-ampere high-reactance circuit. Dotted circle indicates region of recovery voltage transient. B—Experimental lightning arrester of higher follow current tested in same circuits. Oscillograms show failure to interrupt power follow current in the high-reactance circuit

during follow-current flow. Without this there is no assurance that the device will perform properly in service at full-rated voltage.

High-Reactance Power Source

A design which operates properly when connected to a substantial power source may fail to interrupt follow current when energized from a higher reactance circuit, for example the end of a long, low-kva transmission line. In the latter case, the follow current and generated voltage are sufficiently out of phase to result in a more severe recovery voltage transient across the series gap element.

Fig. 3(A) shows oscillograms obtained with a type-*GP* 4.5-kv lightning arrester, first undergoing a standard unit operation with a 10-kiloampere, 12x45-microsecond impulse and, second, undergoing a unit operation in a higher reactance circuit.

Fig. 3(B) shows oscillograms obtained from tests in the same circuits on an experimental 4.5-kv design. By lowering the valve element resistance, thus increasing the follow current, the discharge voltage was lowered and the impulse discharge capacity increased. Operating duty cycle performance was encouraging because performance on the standard test was satisfactory, as evidenced by the left-hand oscillogram of Fig. 3(B). However, this same lightning arrester failed in the nonstandard, high-reactance test circuit (see right-hand oscillogram) since it failed to interrupt the power follow current. This showed its inadequacy for general service duty.

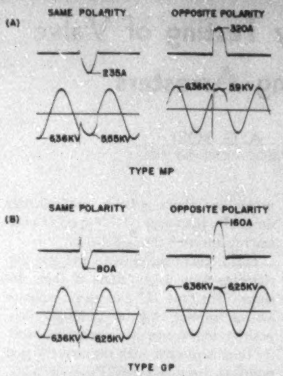

Fig. 4. A—Oscillograms of duty cycle unit operations on type-MP lightning arrester showing effect of relative polarity of the impulse and power voltage on follow-current magnitude. B—Oscillograms of the same tests made on a type-GP arrester

Polarity of Impulse

An operating duty cycle test wherein the initiating surges are the same polarity as the power frequency voltage (as specified in standard operating duty cycle tests) is not the most severe condition for valve-type lightning arresters. If the surge and power frequency voltage are of opposite polarity, the lightning-arrester discharge voltage results in energy storage in the power transformer, which when released may result in a long-duration discharge component through the lightning arrester.[8]

The oscillograms of Fig. 4 illustrate this phenomenon for both type-*GP* and type-*MP* lightning arresters. A standard 10-kiloampere, 12x45-microsecond surge was used to initiate follow current. The left-hand oscillograms were obtained during standard unit operations. The right-hand oscillograms were obtained under identical conditions, except that the surge was timed at 180 electrical degrees later. The latter condition is at least as likely to occur in service. Its greater severity is evident from the relative follow-current magnitudes.

Unfortunately, tests such as these involve considerable risk of undesirable interaction between the impulse generator and power transformer circuits.[9,10] Unless this phenomenon is sufficiently understood and controlled, duty cycle testing with impulse generator and power voltage of opposite polarity cannot be incorporated in lightning arrester standards, even though such testing would be more representative of severe service conditions.

Multiple Strokes

Field studies on a rural distribution system equipped with expulsion-type lightning arresters[11] and on 138-kv lines equipped with protector tubes,[12] showed that 22.5 and 28% of the follow-current operations respectively involved additional intermittent half-cycles of follow current. Boys camera records obtained during other investigations[13,14] showed 37 to 51% of lightning discharges as multiple in nature.

As many as 12 and 15 intermittent half-cycles of follow current on one record were obtained during the field studies on expulsion-type lightning arresters and protector tubes.[11,12] Maximum durations of records in these investigations were 1.83 and 0.67 seconds.

If mere cumulative heat storage within the mass of the valve element and its effect upon performance were the only

factors involved in multiple-stroke operations, the standard operating duty cycle tests would be more than adequate to explore this aspect of service duty. The heating effect of the repeated 10-kiloampere surges is much greater than that resulting from follow current or from any repetitive surges to be encountered in service. However, the elapsed times of 30 minutes and 75 minutes permitted in the AIEE and National Electrical Manufacturers Association standards operating duty cycle tests allow redistribution of heat, within the valve element, which a multiple-stroke operation of 2 seconds' or less duration does not allow. This redistribution of heat within the valve element during the standard duty cycle tests alleviates the formation of local, unstable high-temperature regions within the valve element, which thus gives an unrealistic indication of its thermal stability.

Fig. 5 shows oscillographic records of power follow current obtained during typical tests performed to study the multiple-stroke thermal adequacy of type-*GP* and type-*MP* lightning arresters of 4.5-kv rating. These particular records show 27 and 30 separate unit operations in the elapsed time of less than 2$^1/_2$ seconds. To perform this test, it is necessary to charge the impulse generator which delivers the initiating surge at a very rapid rate. The generator capacity is therefore limited, and the repetitive surge current is approximately 3 kiloamperes of short duration. Although effort was made to maintain the power voltage polarity opposite to that of the initiating surges, this did not always occur.

Impulse Discharge Capacity with Power Voltage Applied

Most lightning arresters in stations and substations are connected to effectively grounded systems, and thus are subject to possible follow-current flow whenever the series gaps are sparked over. For this reason, the lightning arrester impulse and duty cycle test equipment in the Barberton, Ohio, laboratory, see Fig. 6 is so arranged that high current discharge capacity tests can easily be made with power voltage applied to the test piece. The following section describes one such test.

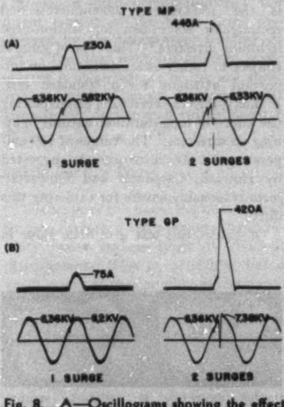

Fig. 8. A—Oscillograms showing the effect of a 10-kiloampere, 12x45-microsecond surge during follow-current flow. Circuit fault current was 500 amperes rms. B—Oscillograms of same test on type-GP lightning arrester

Impulse Discharge During Follow-Current Flow

Separate discharges of multiple lightning strokes are frequently less than 0.01 second apart.[13] It is thus likely that lightning arresters are subjected to discharges while they are already conducting follow current. Investigation of such duty is important because of the following:

1. It may result in considerably increased follow current through the valve and gap elements.
2. A high current impulse discharge during follow-current flow could reduce gap interrupting ability. This might result from

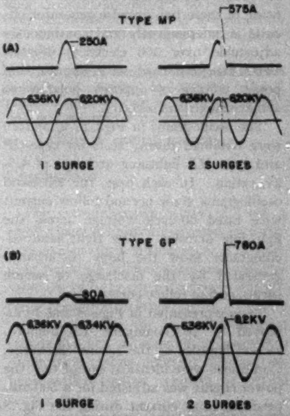

Fig. 9. Conditions identical to those of Fig. 8, except that circuit fault current was 1,000 amperes rather than 500 amperes rms

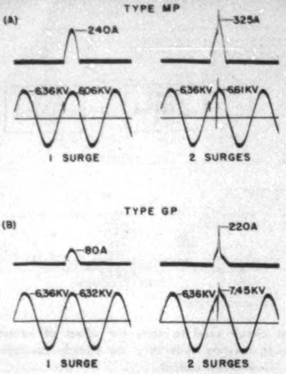

Fig. 10. A—Oscillograms showing effect of 100-kiloampere, 5x9-microsecond surge during follow-current flow on a type-MP lightning arrester. Circuit fault current was 1,000 amperes rms. B—Oscillograms of same test on type-GP arrester

undesirable arc-wandering in the simple multigap designs, like that of the type-*GP* arrester, or from damage to the interrupting chambers of high-performance gaps like that of the type-*MP* arrester.

Fig. 7 shows schematically the circuit used to represent this duty. A low-energy pulse generator is used to initiate follow current. Later, during the same follow-current loop, a second pulse generator triggers the main surge generator which discharges through the test specimen. The firing of these two impulse generator circuits is independently and continuously adjustable over 360 electrical degrees. Tests are performed with impulse and power voltage of opposite polarity to achieve maximum severity.

The oscillograms in Figs. 8, 9, and 10 were obtained during tests on type-*GP* and type-*MP* lightning arresters of 4.5-kv rating. In each case, the left-hand oscillograms show normal follow current with rated 60-cycle voltage across the lightning arrester. The right-hand oscillograms show the large disturbance generated by the discharge of severe surges during follow-current flow.

Tests represented in Figs. 8 and 9 employed a 10-kiloampere 12x45-microsecond impulse as the second discharge. Conditions were identical except that the power circuit was adjusted for a 500-ampere rms fault current during the Fig. 8 tests and a 1,000-ampere rms fault current during the Fig. 9 tests. Tests represented in Fig. 10 employed a 100-kiloampere, 5x9-microsecond impulse as the second discharge. The power circuit was adjusted for a 1,000-ampere rms fault current.

The extreme severity of these tests is obvious from comparison of the left- and right-hand oscillograms. The type-*GP* arrester particularly was subjected to currents of several times normal follow-current flow. Note that the 100-kiloampere impulse imposed less severe long-duration duty than did the longer 10-kiloampere impulse.

The enormous follow-current peaks obtained in these tests may, in part, be the result of interaction between the power transformer and surge generator capacitance. If so, they are in all probability more severe than those which would occur in service with similar surge current, time, and relative power voltage magnitude.

Fig. 11 shows a type-*MP* gap element dismantled after discharging two 100-kiloampere surges during follow-current flow. The design is self-protecting; surges of sufficient magnitude to cause damage to the arc-interrupting chamber restrike at the original spark-over gap. There are four separate arc paths on the electrodes although there were only two separate loops of follow current.

Long-Duration Discharge Capacity

A standard test to explore long-duration discharge capacity of lightning arresters is desirable in the light of present knowledge of service duty.[15,16] One such test is the 150-ampere, 2,000-microsecond rectangular wave test for station-type lightning arresters.[7] This type of surge is subject to rather exact definition, an important attribute for a standard test. It thus fulfills the need for a test exploring the effect of long-duration natural lightning on arresters. The values of 150 amperes and 2,000 microseconds suggested by Howard, Carpenter and Schwartz[15] seem reasonably severe for exploring this duty.

Fig. 11. Gap housing and electrodes from a type-MP lightning arrester dismantled after two 100-kiloampere discharges during follow-current flow as shown in right-hand oscillograms of Fig. 10(A)

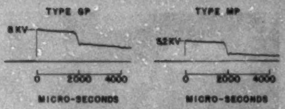

Fig. 12. Oscillograms showing voltage across type-GP and type-MP lightning arresters of 4.5 kv while discharging standard 150-ampere, 2,000-microsecond surges

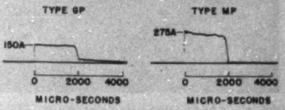

Fig. 13. Oscillograms showing current through type-GP and type-MP lightning arresters of same voltage rating with artificial transmission line charged to same voltage

Of course, this test is of little value in estimating relative switching-surge strength of lightning arresters, since it is defined in terms of current and time. The design engineer must therefore resort to additional tests, since the most severe common surge duty encountered by lightning arresters in station and substation service apparently results from switching-surge operations on long, high-voltage lines and cables.[17,18]

A switching surge is evaluated primarily in terms of voltage, not current. After the surge voltage is sufficiently high to spark-over the lightning-arrester series gaps, the resulting long-duration current magnitude is determined by line voltage, surge impedance, ground resistance, and lightning-arrester resistance. Thus the discharge current will vary greatly among different lightning arresters under identical switching-surge conditions. Figs. 12 and 13 show the effect of arrester resistance on discharge current and voltage. The tests represented by these oscillograms were made with a pi-network artificial transmission line discharging directly into type-*MP* and type-*GP* lightning arresters of 4.5-kv rating. The voltage oscillograms of Fig. 12 were obtained during standard 150-ampere long-duration discharge capacity tests on type-*GP* and type-*MP* lightning arresters. The presence of voltage after 2,000 microseconds indicates that the lightning-arrester resistance was greater than the surge impedance of the artificial transmission line. Note the greater voltage stress across the type-*GP* design. This greater voltage requires a voltage of higher charge on the artificial transmission line to obtain the same current. Actually the type-*GP* design is required to discharge about 1.9 times the energy

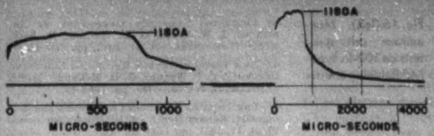

Fig. 14 (left). Oscillograms of current discharge through a 9-kv type-MP arrester. Test simulates 37 miles of 69-kv cable discharging through a 60-kv arrester

required of the type-*MP* on the standard test.

The current oscillograms of Fig. 13 illustrate the same effect in a different manner. In this case, the artificial line was charged to the voltage necessary to generate a 150-ampere surge through a type-*GP* 4.5-kv sample. Direct substitution of a type-*MP* 4.5-kv sample resulted in a 275-ampere discharge. This test, at constant generator charge voltage, would furnish a realistic comparison of switching-surge durability between the two designs because both samples were subjected to the same length of "line" charged to the same switching-surge crest voltage.

The standard 150-ampere, 2,000-microsecond test is probably an excellent choice for evaluating relative durability against long-duration natural lightning. It is a poor criterion for judging relative switching-surge performance.

Cable Tests

High-voltage cable application imposes switching-surge duty of higher current and shorter duration than high-voltage transmission lines because of the lower surge impedance and the shorter length of cables.

The ampere-time oscillograms of Fig. 14 were obtained with the pi-network long-duration surge generator and a 9-kv type-*MP* lightning arrester connected to represent a 37-mile 69-kv 1,000,000-circular-mil cable charged to 2.5 times normal line-to-ground voltage and discharging through a 60-kv type-*MP* lightning arrester. The circuit elements were so chosen that the resulting current and time values were full scale; only the voltage was reduced proportionally to the rating of the test piece. The two oscillograms are of the same current wave recorded to different time scales.

The oscillogram of Fig. 15(A) was obtained with the surge generator and a 12-kv type-*MP* lightning arrester connected to represent 18 miles of 138-kv, 1,000,000-circular-mil cable charged to 2.5 times normal line-to-ground voltage and discharging through a 121-kv type-*MP* lightning arrester.

Fig. 15(B) was obtained under identical conditions except that the duty cycle testing transformer was connected to represent a 30,000-kva, 10% impedance, 138-kv, solidly grounded transformer connected across the cable and lightning arrester. After about 700 microseconds, the discharge was carried by the transformer winding rather than the lightning arrester.

Conditions for Fig. 15(C) were identical with those of 15(B) except that a 12-kv type-*GP* lightning arrester was substituted for the 12-kv type *MP*. Thus, this circuit represented 18 miles of 138-kv cable charged to 2.5 times normal line-to-ground voltage and discharging into a 121-kv type-*GP* lightning arrester in parallel with a large-kva, wye-connected grounded transformer.

Fig. 15(B) and (C) furnish another excellent example, along with Fig. 13, of the way in which the lightning-arrester characteristic itself may determine in large measure the duty to which it is subjected. Thus, although the type-*GP* valve element would soon be destroyed by the surge of Fig. 15(B), it would not receive such a surge under the conditions represented. Its much higher impedance at these low surge currents resulted in the major portion of the surge being discharged by the transformer winding itself. The low lightning-arrester surge current is also evidence of the low surge voltage existing across the transformer and arrester during such switching-surge duty.

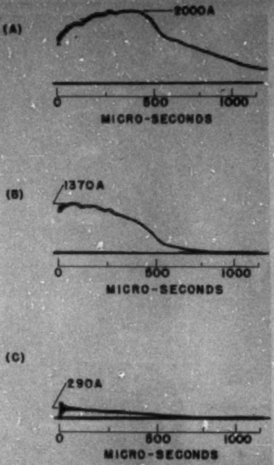

Fig. 15. Oscillograms of tests simulating discharge of 18 miles of 138-kv cable. A—Discharge through 12-kv type-MP lightning arrester. Simulates discharge of cable through a 121-kv type-MP arrester. C—Discharge through 12-kv type-GP arrester with duty cycle test transformer in parallel. Simulates discharge of the cable through a 121-kv type-GP arrester protecting a large, grounded wye-connected power transformer

Other Service Duty

The scope of this paper has been limited to tests exploring lightning-arrester durability under various types of transient disturbances. This is, of course, but a small aspect of the complete performance characteristics of a lightning arrester. Some others, beyond the scope of this paper are the following:

1. Protective characteristics, effect of current and rate of current rise on discharge voltage, stability of discharge voltage under service duty.
2. Effect of external contamination, and effect on series gap current interrupting ability, effect on 60-cycle spark-over voltage (Fig. 16 shows a 300-kv type-*MPR* lightning arrester undergoing a 60-cycle spark-over test while subjected to a nonuniform salt spray of 300-ohms-per-cubic-inch resistivity).
3. Mechanical design, resistance to wind damage, resistance to thermal shock, pressure relief in case of electrical failure, and seal of arrester housing.
4. Stability of grading resistors.

Conclusions

The comprehensive study of even a small aspect of lightning-arrester performance as described in this paper is formidable, requiring full and sometimes imaginative use of large-capacity power and impulse generator facilities.

Tests suitable for lightning arrester standards, i.e., capable of a reasonable duplication among different laboratories, bear rather limited relation to actual service duty.

Conversely, tests approximating service duty, a necessity for the design and development engineer, will often be hard

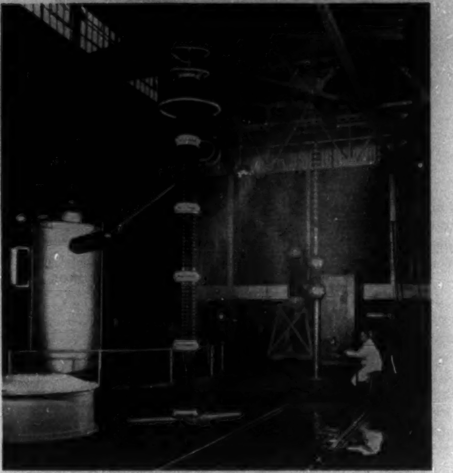

Fig. 16 (left). Nonuniform salt spray tests on 300-kv type-MP lightning arrester

to duplicate among different laboratories. Within the scope of this paper, such tests include the following:

1. Duty cycle testing with full-rated voltage during follow-current flow.
2. Duty cycle testing in high-reactance circuit to explore gap-interrupting ability.
3. Duty cycle testing with impulse and power voltage of opposite polarity, a likely service condition, and one that is more severe than impulse and power voltage the same polarity.
4. Duty cycle testing at the rate of several operations per second to obtain the local, high-temperature regions in valve elements which may occur under multiple-stroke conditions.
5. Impulse discharge during follow-current flow, a possible service condition during multiple strokes.
6. Switching surge tests, i.e., long-duration tests where impulse generator charge voltage rather than discharge current is the criterion for judging performance.
7. Evaluation of wye-connected power transformers on switching surge duty.

Discussion

W. E. Eason (General Electric Company, Pittsfield, Mass.): Similar tests to those described in this lucid paper, as well as others to simulate other possible service conditions, are undoubtedly in use by manufacturers. From time to time, most manufacturers are prompted to devise a nonstandard test to fit particular conditions. Frequently the specially devised test setup and procedure involve, as the authors observe, testing techniques or possible interaction of circuit components to a degree which would render duplication among different laboratories most difficult. Moreover, the test may have been devised purely as an experimental or exploratory general test or to investigate the performance of a particular design change in one of several models of arresters. For these or other reasons, the manufacturer will refrain from suggesting a change in the Standards. Accordingly, the authors have clearly stated that the tests described in this paper are not suggested as revisions of the Standards.

Acceptance of, or a change in, an existing test is usually a long and difficult procedure because of a natural reluctance to discard the vast amounts of experience and the data of an existing test, and because of the necessity for expensive retesting if a change is accepted. Also, opposition to a proposal for a new test may come from another manufacturer with a slightly different test to simulate the same service condition. Then all manufacturers must make tests using one or more of the proposed methods. All this is expensive and time-consuming, and inevitably effects a rise in the prices of lightning arresters. It is therefore desirable that such proposals be introduced only if there is a clear need for amplification of the Standards.

I do not imply that none of the authors' suggestions warrant consideration as a possible change in the Standards. The one proposing that some duty cycle tests be made with rated voltage held during flow of follow-current is under consideration for inclusion in the forthcoming revisions of United States industry standards as well as in the proposed International Electrotechnical Commission standard. The AIEE lightning arrester standards are nearing completion after an intensive 5-year study. It is not too early to start work on the accumulation of data, to determine whether changes are justified.

I agree that long-duration test data in addition to the standard long-duration discharge tests are required to give a quantitative basis for evaluating the adequacy of a lightning arrester to discharge long lines or cable circuits. Our own continuing program to secure such data on our various designs confirms this. However, I must take issue with the authors' statement that the standard long-duration test for station-type arresters is a "poor criterion for judging relative switching-surge performance." The 1951 paper (see reference 15 of the paper) which proposed this 150-ampere, 2,000-microsecond long-duration discharge test contains evidence that the test does distinguish between arresters which withstood repeated switching-surge duty and those which failed on the same switching-surge duty. No claim has been made that the standard long-duration test exactly represents either switching-surge or long-duration lightning duty. It has been demonstrated as a test capable of standardization between independent laboratories to demonstrate the long-duration, low-current strength of an arrester. Moreover, it is a reasonable criterion for distinguishing between arresters as to their ability to withstand both long-duration lightning discharges and switching surges.

W. S. Price (American Gas & Electric Service Corporation, New York, N. Y.): Electric equipment in service on a power system is exposed to such a wide variety of electrical conditions that it would seem impossible to simulate all of these conditions in the laboratory during design work. For this reason, the actual worth of an equipment design has to be determined in many cases by the performance of that equipment in service over a period of years. However, it is inefficient and uneconomical to place equipment in service with so many "ignorance factors" included in the application that the equipment is not used at its full capability

In this timely paper, the authors describe some laboratory tests on lightning arresters exposed to various transients which might be expected to occur in service, and have pointed out that such tests are complicated and expensive and probably not capable of duplication among different laboratories. Nevertheless, such tests are extremely worth while, and should be encouraged by all equipment users, since they should ultimately permit the use of equipment on the most economical basis.

A. M. Opsahl (Westinghouse Electric Corporation, East Pittsburgh, Pa.): This is a good analysis of the problems and phenomena associated with the testing of lightning arresters. The whole range of surge conditions in service is formidable, and only a few conditions can be selected for laboratory test. In the case of surge currents, the median of the crest currents measured through arresters in service has been 800 amperes in about 5,000 measurements. In setting up tests for discharge voltage in the standard, currents of 5, 10, and 20 kiloamperes were selected with a 10x20-microsecond wave shape. These currents are about six to 25 times the median current in service. These test currents also provide range of rate of rise of current in the upper band of those that can be expected in service. The discharge voltage across the valve arrester does not change very much with various currents or with various rates of rise of current, as the standard test demonstrates.

Power follow currents and switching-surge currents fall in a lower level than the impulse currents expected from lightning. Perhaps more standard tests on the valve element in this region of current will be useful. In the past, they have been of interest only to the designer. As has been stated, the valve arrester discharge voltage does not change much with current and, conversely, the current, such as power follow, changes rapidly with applied voltage. The current in this part of the arrester characteristic rises about as the cube of the applied voltage according to the paper.

Lightning surges can occur during any part of the 60-cycle wave. An impulse current of the same polarity as the power voltage has a smooth transition from impulse current to follow current. Impulse discharges through the lightning arrester too low on the power voltage wave, too short in time, or of opposite polarity to the power voltage wave may not establish follow current through the arrester. This is a condition that can occur in service but it may be misleading if standard tests are based on such conditions. On opposite polarity power and test impulse, as the voltage across the arrester gap goes through a transient zero, a gap of high-interrupting or deionizing ability tends to quit and not restrike as the voltage rises to or overshoots the power voltage.

If the arrester gap does restrike, the energy to be absorbed is that stored in the test circuit transformer and surge generator capacitor. This is a function of the length of the surge, the capacitance of the surge generator, and the reactance of the power transformer. The duty on opposite polarity impulse and power may be more severe than testing on the same polarity but the results may also be misleading. Similarly, testing too low a voltage sample may also be misleading so the standards require that two voltage ratings be tested. For our routine power follow testing we have used longer duration current waves than those specified in the discharge voltage test. They are more certain to establish follow current and they also test for durability on the longer duration surges measured in service.

E. Beck (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Several years ago some tests were made, the results of which we should like to contribute to this excellent paper. The object of the tests was to secure data pertaining to the wave shape of the current discharged through a lightning arrester from a charged conductor, in the expectation that this would resemble what might happen in the case of switching surges produced by interrupting the charging currents to an idle line or cable. I am not sure that this actually represents what happens for all switching surges, because there are many variables that enter the matter, one of which is whether the arrester is on the line or the source side of the circuit breaker and whether a voltage sufficient to discharge the arrester appears at the arrester before or after the arc in the circuit breaker is interrupted, and also what the arc characteristics are. It seems to me that variations of these cases occur. There exists a lack of factual data on the character of switching surges on systems and of the currents that arresters discharge if they are operated by switching idle lines or cable. Before jumping to conclusions, it

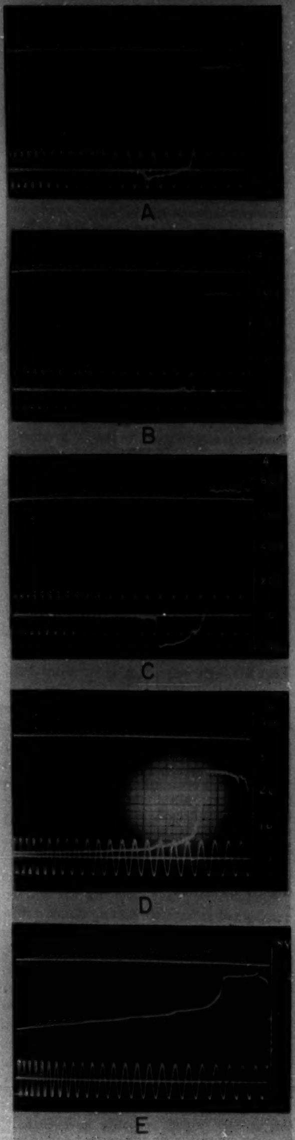

Fig. 17. Oscillograms of tests. A—Test 1. B—Test 2. C—Test 3. D and E—Test 4

seems to me we should know the facts.

Our tests may resemble the case of the arrester connected on the line side of the circuit breaker, with the line or cable charged by switching, to a high enough voltage to discharge the arrester. Also, at the moment that the arrester sparks, the circuit breaker has already interrupted so that the source is disconnected from the line. This may be the minority case, but it is the most severe as far as the arrester is concerned because it is on its own and has to dissipate all the energy that has been put into the line or cable.

The procedure in the test was to charge the cable to a definite voltage, then switch it on to a lightning-arrester element thereby discharging the cable through this arrester element. No arrester series gap is included. The test results at least show the wave shape of discharge current and the effect on the wave shape of differences in arrester impedance. The cable used was 966 feet long with a lead sheath and a surge impedance of 25.3 ohms. The cable sheath was grounded at each end and in the middle. It was charged by a rectifier.

Test 1

The cable was charged to 16 kv and discharged through a 22-ohm resistor. Fig. 17 shows the current-time oscillograms for the tests. Time runs from right to left in all the oscillograms. The wave shape in Fig. 17 (A) is practically square as is to be expected because the 22-ohm resistor almost matches the cable impedance of 25.3 ohms. The voltage appearing across the resistor in this case was 8 kv. Since the resistor's resistance was slightly less than the cable impedance, there is a small oscillation of reverse polarity.

Test 2

The cable was again charged to 16 kv and was discharged through a single station-type arrester block, the element of a 3-kv arrester. The wave, shown in Fig. 17 (C), is again practically square, because the block impedance approaches the cable impedance. The voltage across the arrester block was again 8 kv. When the current decays, the block impedance increases and there are a few added pulses of current of the same polarity as original pulse. Actually, the voltage oscillogram, not shown here, indicates that the following pulses are slightly oscillatory.

Test 3

The cable was charged to 30 kv, higher than in test 2. It was discharged again through one block. The current is now about $2\frac{1}{2}$ times higher. The voltage was about 9 kv. The initial pulse is again square, as shown in Fig. 17 (C). It is followed by a negative pulse. The arrester impedance is lower because of the higher discharge pulse.

It appears from these tests that switching surge voltage magnitude has an effect. In an actual arrester containing series gap, the arrester would probably have ceased to carry current when the current and voltage pass through zero.

Test 4

The cable was again charged with 30 kv and discharged this time through three station blocks in series, the element of a 9-kv arrester. Because of the fogging on the current oscillogram of Fig. 17 (D), the voltage oscillogram, Fig. 17 (E), is also shown. Initially the wave is square, but then, since the impedance of the three blocks in series is higher than the cable impedance, the discharge has a relatively long tail that looks like the discharge of a capacitor through a resistance.

Again, it is not the purpose of this discussion to settle the problems posed by switching surges. The real purpose is to point to some of the phases of the problem and emphasize that some fundamental data on the character of switching surges are needed to tackle the problem realistically. It should be possible to obtain such data in the field more easily than recording of lightning surges. Then some single case should be selected as a criterion.

H. A. Cornelius (Commonwealth Edison Company, Chicago, Ill.): The authors have effectively demonstrated a weakness in existing lightning arrester duty cycle test standards. In making the standard duty cycle test a 60-cycle voltage equal to the lightning arrester's voltage rating is applied, as well as the 10- by 20-impulse current wave. Present standards permit the 60-cycle voltage to decrease up to 10%, while follow-current flows through an arrester.

Several undesirable effects occur because rated arrester voltage is not maintained while power follow current flows. These effects are:

1. The magnitude of the follow current is understated, i.e., by allowing the voltage to drop to about 93%, a follow current of 230 amperes was obtained in the test. When the voltage was maintained at 100% while follow current flowed, a current of 295 amperes was obtained. This is a difference in follow current of 28%.
2. The magnitude of follow current secured under this condition is not representative of system performance requirements. System voltage will be maintained and may even be somewhat above normal on most large systems; so an arrester must be able to "seal off" against rated voltage.
3. The full heating effect of the follow current at rated voltage is not secured. Obviously the heat produced by a 128% current squared, is greater than for a 100% current squared.

Progressive improvements in the duty cycle test standards for arresters, however, have been made gradually over the years. The present AIEE Standard No. *28*,[1] permits a 10% drop below the rated voltage of an arrester, while 60-cycle power follow current flows. The present National Electrical Manufacturers Association standard, (see reference 7 of the paper) issued in March 1952, requires the use of a larger 60-cycle voltage source, one capable of delivering 500- to 1,000-ampere rms fault current to help with this problem. The weakness of the present standards, so effectively demonstrated by the author, of permitting the 60-cycle voltage to decrease during the flow of follow current, has been corrected in the draft of a new AIEE Standard No. *28*. In this draft, the 60-cycle voltage is not permitted to be less than the arrester's rated voltage during the flow of 60-cycle follow current.

Securing a test for lightning arresters which simulates the effect of repeated surges and power follow-current interruptions, such as occur in the field, on the thermal stability of arresters has been an objective for several years. The present standard duty cycle test is a poor approximation of field conditions, because of the 1-minute delay specified between successive tests in the series. Also, it is far less severe because the cumulative heat produced over a 30-minute period is less than that which may occur in service in 1 second, when a many-component stroke occurs. When 30 duty cycle tests are applied in about 2 seconds, however, as in the authors' description, the test is considered adequate and it would be desirable to include it in the revised edition of AIEE Standard No. *28*.

The present standard low-current long-duration discharge current test for arresters could be made more valuable to users and less expensive for manufacturers, by amending the method of making it. That is, instead of applying a rectangular-wave 150-ampere crest current for 2,000 microseconds to a station-type arrester, for example, as required by present standards, apply sufficient voltage to a given arrester to cause 150 amperes to flow for 2,000 microseconds. In this way, both the durability of an arrester when exposed to natural lightning and its switching-surge withstand ability can be tested under comparable conditions in all laboratories. The performance of the arrester in the field after surge voltage has caused spark-over of the series gaps, of course, will be somewhat different from that in the laboratory. In the field the long-duration discharge current magnitude will depend on: 1. the line voltage applied; 2. the line surge impedance; 3. the arrester's resistance; and 4. the arrester ground lead and ground grid resistance, as was mentioned in the paper. These factors, however, would not decrease the value of making tests on a simplified circuit in the laboratory. In closing, I wish to congratulate the authors on providing some very timely and useful information.

Reference

1. Lightning Arresters for Alternating-Current Power Circuits. *AIEE Standard No. 28*, May 1944.

J. W. Kalb and **A. G. Yost** (Ohio Brass Company, Barberton, Ohio): The authors appreciate the comments and questions of the discussers. We are certainly in agreement with Mr. Eason regarding the general objectives as well as the limitations of lightning arrester standards. Furthermore, we do not necessarily believe that any single long-duration discharge test, suitable as a standard test, can be found which is significantly better than the present 150-ampere, 2,000-microsecond test. However, a test defined in terms of current is next to meaningless when investigating switching-surge durabilities, unless all lightning arrester impedances in this current range are identical. The situation is somewhat analogous to a duty cycle test wherein the power frequency test voltage would be adjusted to give the same follow-current for all arresters. It is true that the service records of the more modern arresters, some of which meet the 150-ampere 2,000-microsecond test, are considerably better than those of earlier types. This may well be partly because of the greater immunity to long-duration natural lightning, as indicated by the ability to pass this test. However, other aspects of performance were also improved during this period, for example, the development of adequate moisture seals practically eliminated failure due to corrosion, which may have been the largest single cause of arrester failure.

We appreciate Mr. Price's interest in the tests. Of course those described in the paper represent the idea of only one manufacturer regarding the aspects of transient durability worthy of investigation. We hope this paper will encourage others to publish similar work.

We agree with Mr. Opsahl that duty cycle testing with the impulse and power frequency voltage of opposite polarity can be misleading. If power follow current is not started, conditions must be altered until it is. Once this has been done, conditions are almost certain to be more severe than those which could occur in service with presumably identical circuit parameters. There can be no doubt that the industry is far from being able to make opposite polarity duty cycle tests in different laboratories with any hope of comparable results.

We also agree that the current wave of longer duration (for example, one of 12x45 microseconds) constitutes a more severe test than does the 10x20-microsecond wave. It is used as part of our routine quality control testing.

Mr. Beck's discussion and accompanying oscillograms are most pertinent to the subject of switching-surge discharges, particularly since 966 feet of real cable were used, while the tests in the paper were made with simulated cable.

The similarity of results is gratifying, as can be seen by comparison of Fig. 17 (D) with Fig. 14. In both cases tests were made with 9-kv lightning arrester elements. The current and duration shown in Fig. 14 are much higher than those of Fig. 17 (D) but this is because the authors were attempting to represent higher cable-charging voltage, lower surge impedance, and greater length (37 miles) than were used in Mr. Beck's tests.

Mr. Beck has also shown quite aptly the effect of the arrester valve element characteristics upon switching-surge discharge magnitude, the only difference between the tests represented in Fig. 17 (B) and (C) being the number of valve blocks. This is similar to Fig. 13 of the paper, wherein the only difference between the two test conditions was that type-*GP* and type-*MP* elements were used.

We agree with Mr. Cornelius that the present duty cycle test is inadequate for exploring thermal stability or repetitive discharge strength. It must be pointed out that a repetitive discharge test could employ only weak surges for the initiation of follow-current, because impulse generators capable of delivering 10-kiloampere, 10x20-microsecond discharges cannot be charged with sufficient speed to make this test. As a multiple-stroke test, however, this constitutes no limitation, since successive current peaks of multiple discharge strokes are generally of low magnitude.

Such a test would explore a different service duty from the present standard duty cycle test wherein the repeated application of 10-kilocycle discharges constitutes a significant part of the over-all test severity. Therefore, a multiple-stroke or thermal-stability test, if employed, would supplement rather than replace the existing standard duty cycle test.

An Incremental Cost of Power-Delivered Computer

E. D. EARLY

W. T. SHREVE
NONMEMBER AIEE

THE integrated Southern Company System consisting of the Alabama Power Company, the Georgia Power Company, the Gulf Power Company, and the Mississippi Power Company serves an area of nearly 100,000 square miles and supplies a load of approximately 3,000,000 kw. Power supply sources available to this vast system consist of 18 major hydro plants, 15 major steam plants, and 11 interconnections with 6 neighboring systems. For many years, the operation of these power supply facilities has been co-ordinated through a central office known as the Power Pool Office functioning through the dispatching organizations of the four operating companies.

Co-ordination of power supply facilities was carried out by means of power supply schedules prepared in advance and supplied to each of the dispatching offices. Although important savings were realized from such co-ordination, it was recognized that advance scheduling of the operation of the various sources could not result in maximum economy since such schedules were based upon anticipated system conditions rather than those actually existing at the time. As the system load became larger and the number of generating plants increased, the additional savings which could be realized by closer supervision of power supply increased and management decided to establish a central power co-ordination office to be manned 24 hours a day to obtain maximum efficiency in such co-ordination.

During the planning and construction of this power co-ordination office, new procedures were studied to obtain increased economy of power supply with the new organization. It was concluded that the most important single improvement that could be made was to find a means of properly including the effect of transmission losses upon system power supply costs. A survey of the accomplishments in this field showed that the only existing method of doing this was by means of scheduling generation some 24 hours ahead on the basis of curves representing incremental transmission losses for a number of typical system conditions. This procedure did not offer a satisfactory solution to the problem since one of the principal reasons for establishing the new office was to eliminate advance scheduling of power supply. If the power supply co-ordinator (PSC) could take into account system conditions such as sytem load, interchange with other systems, and maximum and minimum capability of each of the generating units as they change, it would be a great aid in permitting schedules to be changed quickly to meet changed conditions and thus improve the economy of power supply.

Computer Developed to Fulfill Need

The Southern Company personnel then conceived the idea of and developed the circuits for an analogue-type computer which would quickly determine the incremental cost of power delivered for each generating unit based upon system conditions actually existing at the time. This conception embraced the idea that all telemetered information such as tie-line loadings, output of regulating plants, and output of other major generating plants should be fed directly to the com-

---

Paper 55-141, recommended by the AIEE System Engineering and Computing Devices Committees and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 19, 1954; made available for printing December 6, 1954.

E. D. EARLY is with Southern Services, Inc., Birmingham, Ala., and W. E. PHILLIPS and W. T. SHREVE are with Leeds & Northrup Company, Philadelphia, Pa.

puter with means being provided for manually supplying to the computer other required information on current system conditions. To simplify the PSC's problem in determining the proper loading of each generating unit so as to minimize the cost of power delivered to the substations, meters showing per cent of power delivered and incremental cost of power delivered were to be located directly in front of him with selector buttons provided for selecting any unit on the system. When a selection is made the meters should provide an indication of these quantities for the selected unit. To realize these objectives, an incremental cost of power-delivered computer was designed and constructed, and has been in service on the Southern Company System since June 1954.

Operating Principles

The computer automatically determines the incremental percentage of power delivered from each source, as selected, and simultaneously calculates the incremental cost of power delivered from a particular generator located at the source. A high percentage of the required information is fed into the computer automatically and the data are "read out" manually by means of a series of push buttons provided on the center section of the computer, as shown in Fig. 1.

The only information required from the power system for computing the incremental transmission loss is the magnitude of the power at each of the sources. It should be noted that, in the case of tie lines, both magnitude and direction of power flow are required since power may flow in either direction. Large industrial loads which do not conform to the normal load pattern are introduced into the computer as sources of negative generation. This effectively prevents these loads from distorting the normal load pattern.

The magnitudes of the power in the sources which are subject to rapid or unpredictable variations are fed into the computer automatically by retransmitting means in the telemetering receiving recorders. The recorders are located on the panels which are in the background of the computer, as shown in Fig. 1. The megawatt values of the sources which are not fed in automatically are set by means of manual dials in accordance with the information received on the teletype equipment located to the right of the computer console.

The computer has been built to accomodate 30 sources although at the present time only 23 sources are required to represent the system. In some instances a source may be made up of several generating stations which are in close proximity, or it may consist of a generating station, a nonconforming load, and a tie line to an adjacent system.

The operation of the computer is relatively simple in that the operator merely pushes the button corresponding to a particular generator and the computer automatically displays the incremental percentage of power delivered from that source on one indicating meter and the incremental cost of power delivered from that generator to the load centers on a second indicating meter. These two meters, as shown in Fig. 1, are located centrally with respect to the push buttons and are calibrated respectively in per cent and mils per kilowatt-hour. The incremental cost of power delivered will hereinafter be referred to as λ. It should be noted that only the incremental percentage of power delivered is calculated for tie lines to foreign systems. The incremental cost of power delivered or, stated more exactly, the incremental cost of power delivered to the load centers is defined as the additional cost of the next increment of power delivered to the load centers taking into account not only the incremental cost of generating power at the station bus but also the attendant change in transmission loss involved in transmitting this power to the load centers.

The computer is integrated into system operation in the following manner so as to realize, as nearly as is practicable, equal λ values for all the generating units. If, e.g., additional load comes on the system, the generation of the regulating station, which is a hydro plant, is automatically increased by the action of the frequency-biased tie-line load control so that the area requirement is returned to zero. As the regulating plant approaches its upper limit of regulating capacity, the PSC redistributes the load change on the remainder of the generating units on the system so that the regulating plant generation is approximately centered in its regulating range. To determine the division of the load increase between the remaining generators which are not on automatic control, the PSC, by means of manual dials provided on the computer, inserts an increased value of generation for each of the units which are in a position to accept a load increase.

It should be noted that units having a low cost, or which are favorably located, or units which may be constrained for any reason may be operating at values below the power system λ. Units with values of λ lower than the system λ, or which are constrained, will be operating at maximum outputs and, since the outputs of these units cannot be increased, the PSC need only take into account the λ's of the nonconstrained units. After reading the λ's for the nonconstrained generating units, the PSC selects one or several of the units, the outputs of which should be increased to bring them more closely to the average value of the λ's on the nonconstrained units. The amount of load increase required for each generating unit is then determined by adjusting the manual dial to the proper value which will increase the λ of that particular generating unit to the approximate average of the λ's on the nonconstrained units. For those cases where the output of a station is telemetered to the PSC office and fed automatically into the computer, it is only necessary to snap a toggle switch from the "telemetering" to "manual" position to operate the manual dials for the various generating units in the station. After the manual dials have been adjusted to determine the megawatt increase for the various units in that par-

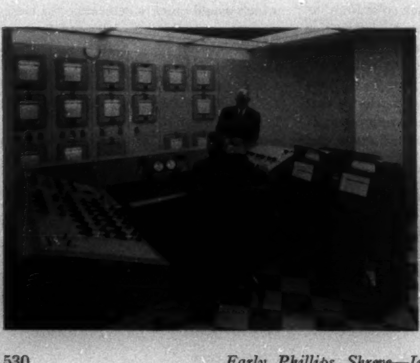

Fig. 1. Incremental cost of power-delivered computer

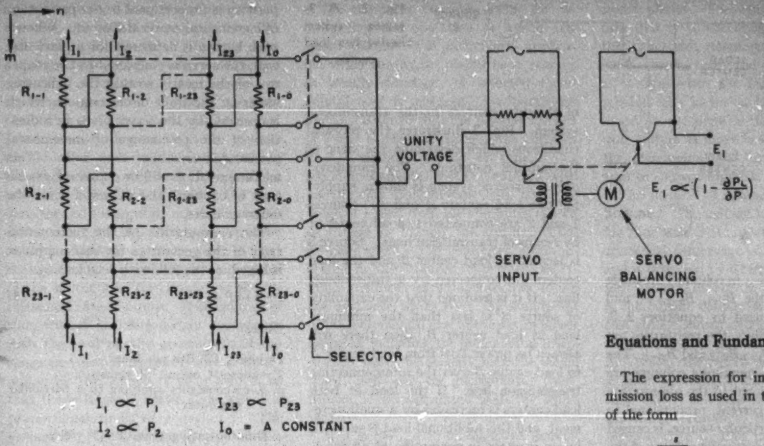

Fig. 2. Schematic diagram of matrix and incremental pescentage of power-delivered servo

ticular station, the toggle switch can be returned to the "telemeter" position. In many cases there are only a few units which economically enter into a single load increment and the entire operation outlined in the foregoing can be performed in approximately 1 minute. The same general procedure is used if the system load decreases except that the required generation changes are determined on the basis of decreases in generation.

Some of the stations on the Southern System burn either coal and/or gas in the steam generators. The gas burned is so-called dump gas and is interruptable on very short notice. Since, in general, the cost of gas is less than that of coal, a station will have a relatively low incremental rate when burning gas. When the gas supply is interrupted the PSC turns the fuel selector switch from gas to coal and the computed value of the incremental cost of power delivered automatically reflects the higher cost of the coal fuel. This will cause a change in the value of λ as read from the computer, and a readjustment of the generation of this and other stations will be required to equalize the values of λ.

The computed value of the new generation requirement, as dictated by either a system load change or a change in the type of fuel, is dispatched to the station or stations by means of the teletype referred to previously. By using the computer in the manner just described, the λ's of all nonconstrained generating units are maintained at essentially equal values. It should be noted that equal values of λ should not be interpreted to mean that λ has a constant value. The value of λ for the power system will vary as a function of total system generation. This is a well-recognized principle of electric power system operation.

The computer may also be used for obtaining an evaluation of the incremental cost of power delivered to neighboring systems and of the incremental value of power received from neighboring systems. The generator or generators supplying power to a neighboring system are those within operating range which are operating at essentially equal incremental cost of power delivered to the load centers. The λ of these generators is the system λ which was earlier described. The λ of power delivered over or received from an interconnection is the system λ multiplied by the per-cent power delivered (expressed as a decimal) as read from the computer for this interconnection. The average incremental cost of power delivered or the average incremental value of power received at an interconnection is the average of the incremental cost or incremental value as determined in the foregoing for the condition when no power is being received or delivered over the interconnection and the incremental values when such power is being delivered or received.

It has been found convenient to log the values of λ and incremental percentage of power delivered at variable intervals so that the PSC can follow the system trend and be prepared to allocate the next change in generation to the proper generator or generators. At times when the system load is relatively constant, the interval between loggings can be increased.

Equations and Fundamental Circuitry

The expression for incremental transmission loss as used in the computer are of the form

$$\frac{\partial P_L}{\partial P_m}=2\sum_{n=1}^{s}B_{mn}P_n+B_{m0} \tag{1}$$

where

s = number of sources
m = row index which assumes all values of whole numbers from 1 to s
n = column index which assumes all values of whole numbers from 1 to s
P_m = power of source m
P_n = power of source n
P_L = total transmission loss
B_{mn} = constants determined by the system characteristics
B_{m0} = constant based on the incremental transmission loss at zero system generation

The Southern System has 23 sources so that the expressions for the incremental transmission loss for particular sources are as follows:

source 1

$$\frac{\partial P_L}{\partial P_1}=2B_{1-1}P_1+2B_{1-2}P_2+2B_{1-3}P_3+ \ldots +2B_{1-23}P_{23}+B_{1-0} \tag{2}$$

source 2

$$\frac{\partial P_L}{\partial P_2}=2B_{2-1}P_1+2B_{2-2}P_2+2B_{2-3}P_3+ \ldots +2B_{2-23}P_{23}+B_{2-0} \tag{3}$$

A matrix, which is shown schematically in Fig. 2, is used in the computer to obtain analogue voltages proportional to the incremental transmission loss for each of the individual sources as typified by equations 2, 3, and 4. The resistors R_{1-1},

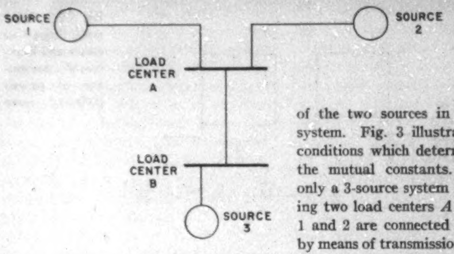

Fig. 3. A 3-source system having two load centers

$R_{2-1}, \ldots$, and R_{23-1} in column 1 are made proportional to the B_{1-1}, $B_{2-1}, \ldots$, and B_{23-1} constants used in equations 2, 3, and 4. In column 2, the resistances are proportional to B_{1-2}, B_{2-2}, and B_{23-2}. The resistances in the remaining columns are similarly proportional to the appropriate B constants. A current, proportional to the power of a particular source, is caused to flow through a particular column of the matrix. For example, the current I_1 in column 1 is proportional to P_1, and the current in column 2 is proportional to P_2, etc. A measure of the incremental transmission loss of a particular source is obtained by summing the voltages of a particular row. For example, the sum of the voltages across row 1 is $I_1R_{1-1}+I_2R_{1-2}+\ldots+I_{23}R_{1-23}+I_0R_{1-0}$ which sum is proportional to the incremental transmission loss for source 1, as expressed in equation 2. In a like manner, the sum of row 2 is proportional to the incremental transmission loss for source 2. Similarly summing over the other rows, one at a time, yields values of the incremental transmission losses for the remaining sources. When a particular source is a tie line to a neighboring system, the direction of current flow through the column reverses with a reversal of power flow.

It will be of interest to examine the B constants in some detail so that a physical significance can be assigned to them. The actual determination of these constants is developed by Early, Watson, and Smith.[1] The constants designated as B_{1-1}, $B_{2-2}, \ldots B_{23-23}$ are termed self-constants and their values are a measure of the effect on the incremental transmission loss of a given source caused by a change of power in that source. These constants are always positive in sign. The constants designated as B_{1-2}, B_{1-3}, B_{2-3}, and other similar constants where the subscript involves two sources are referred to as mutual constants. These relate the effect of a change in one power source to the incremental transmission loss of a second source. Their values may be either positive or negative depending on the relation of the two sources in the transmission system. Fig. 3 illustrates the physical conditions which determine the signs of the mutual constants. For simplicity, only a 3-source system is shown, supplying two load centers A and B. Sources 1 and 2 are connected to load center A by means of transmission lines. Source 3 is located at load center B and the load centers are connected by a transmission line. If it is assumed that the capability of source 3 is less than the minimum load at load center B, then there will always be power flow from load center A to load center B over the interconnecting transmission line. If the load at both load centers is increased by a small increment, and this additional load is supplied by an increase in generation at source 1, the incremental transmission loss for source 2 will be increased.

This is because part of the power of source 2 is being transferred to load center B over the transmission line connecting the two load centers. Since the level of power flowing over this transmission line has been raised, the incremental transmission loss associated with source 2 is also increased. If, under similar conditions, the generation is increased at source 2, the effect will be an increase of the incremental transmission loss for source 1. Thus, the mutual constants relating sources 1 and 2 are positive. If the increment in load at the load centers is supplied by increasing generation at source 3, this will decrease the power flow over the transmission line connecting the load centers and thus decrease the incremental transmission loss associated with sources 1 and 2. Since the incremental transmission losses of sources 1 and 2 decrease with an increase of generation at source 3, the mutual constants between sources 1 and 3 and also between sources 2 and 3 are negative. It is not to be implied that the foregoing explanation is intended as a rigorous proof regarding the signs of the mutual constants but is merely intended to give a physical significance to the mutual constants.

Referring to Fig. 2, the voltage derived from a row of the matrix is substracted from a voltage representative of unity and this resultant voltage is measured by an a-c potentiometer servo unit so that the position of the output shaft of the servo is proportional to unity minus the percentage of incremental transmission loss. Stating it another way, the servo shaft position is proportional to the percentage of incremental power delivered. When a push button is depressed for a particular unit, the servo is connected to the proper row of the matrix so that the indicating meter on the front of the console, which is operated by the servo, gives an indication of the percentage of incremental power delivered by that unit. This measurement, as will be explained, is also used to compute the values of λ for the different units.

The computation of the incremental rates of the generators for this computer is based on the following relations

$$I=a+bP+cP^2 \tag{5}$$

where

I = input, 10^6 Btu per hour
P = kilowatt output of generator
a, b, c = constants applying to a particular generator

Differentiating equation 5 yields

$$\frac{dI}{dP}=b+2cP \tag{6}$$

which is the expression for the incremental rate of a particular generator. It should be noted that, when equation 6 is plotted with kilowatts as the abscissa and 10^6 Btu per kilowatt-hour as the ordinate, it describes a straight line of intercept at b and a slope of $2C$.

When the generators in a multiple unit station have the same characteristics, only one incremental rate circuit is used for the station. The computer automatically divides the total generation equally among the generators in service and all computing is done on a unit basis. When a station has units of different characteristics, a separate incremental rate circuit is provided for each type of unit. For example, Gorgas Station, which has a total of eight generators, is provided with four separate incremental rate circuits. As indicated, the incremental rate curves in this installation were represented by a straight-line relationship. The principles of computing are such that incremental rate circuits can be arranged to express this relation as a series of connected straight lines of different slopes and intercepts. By this method any of the typical incremental rate curves can be followed quite closely. To convert to cost, both sides of equation 6 can be multiplied by f, the cost per 1,000,000 Btu, and the equation becomes

$$\frac{dIxf}{dP}=\frac{dF}{dP}=(b+2cP)f \tag{7}$$

Equation 7 states that the incremental

cost per kilowatt-hour is the product of the sum of b and $2cP$ multiplied by the cost per 1,000,000 Btu. Separate cost dials are provided for each station for each type of fuel which may be used in the steam generator. Some of the stations may be using both gas and coal simultaneously in a single steam generator, in which case the dial is selected for the particular type of fuel which is to be varied as a function of load. The cost dials for the steam units are calibrated in cents per 1,000,000 Btu and may be readily adjusted as the price of fuel changes. Fig. 4 is a schematic diagram of the circuit used for computing the incremental rate of a unit. The contact of slide wire S is positioned in accordance with the load on the generator and the range in volts of the slide wire is determined by the setting of slide wire S_1 so that the voltage E_1 across slide wire S is proportional to $2c$ of equation 7. The voltage E_2, Fig. 4, is thus proportional to the $2cP$ term. Slide wire S_2 is so positioned that voltage E_3 is proportional to the b term of this same equation. The sum of E_2 and E_3 is in turn proportional to $(b+2cP)$, and it is necessary to modify this sum by the cost factor f to obtain a voltage representative of the right-hand term of equation 7. This is done by applying the sum voltage to slide wire S_3 and adjusting the position of its contact in accordance with the f term, as shown in Fig. 3. The voltage E_4, which is the resultant output after the foregoing operations, is representative of the right-hand term of equation 7, or the incremental rate in mils per kilowatt-hour of the unit.

The computer provides means for coordinating the operation of hydro and steam plants. It is particularly applicable when the hydro plants have storage or weekly pondage. A selected incremental cost is assigned to a particular hydro station so that the desired amount of water is released through the turbines in a designated period of time. This pseudoincremental cost is combined with incremental transmission loss, and the value of λ read from the computer is used as a basis for loading the station, as described earlier. The computer, when operated in this manner, effectively determines the most advantageous time to use the available water from the standpoint of the incremental cost of the steam power replaced, including the incremental transmission losses associated with the steam plant, and also the incremental transmission losses associated with the hydro plant.

If it is desired to increase the amount of water released over a given period of time, the cost dial is set at a lower value which will result in a lower value of λ. This means that the station will be generating for a greater number of hours during the course of a day's time. Assigning a greater cost will result in an increased value of λ and, consequently, the amount of water released will be decreased. When it is desired to release the maximum amount of water through the turbines, the cost dial is set at zero which will normally result in the plant being fully loaded for all values of system load. Operation on some systems is based on peaking hydro plants at time of system peak to limit generation at higher cost steam plants. The computer may dictate that it is advantageous to increase the higher cost steam generation at peak loads and increase the hydrogeneration at a time when the incremental transmission loss factor is lower.[2,3] This is based on the premise that the transmission system is most heavily loaded and the incremental loss is greatest at the time of the system peak.

The method of computing λ is shown in Fig. 5. The voltage across the measuring slide wire S is proportional to the incremental percentage of power delivered, and is provided by a retransmitter on the servo shown in Fig. 2. The voltage E_4 is the output voltage of the incremental cost circuit shown in Fig. 4, and is to be balanced by the positioning of slide wire S. When the servo is balanced, the angular position of the contact arm of slide wire S is a measure of λ. For this particular computer, the range of the servo is 0 to 15 mils per kilowatt-hour. The balanced position of the slide wire is directly proportional to E_4 and inversely proportional to E_1. For example, if the voltage E_1 is doubled in value, with E_4 remaining constant, the servo will be balanced at one-half of its previous angular position. Essentially this servo is of the ratio type, which measures the ratio of the incremental rate of the generator to the incremental percentage of power delivered.

All of the variable factors in the computing circuits including the matrix elements are adjustable over wide limits of permit, taking care of future conditions which may result from changes on the power system. Factors, such as fuel cost, which may vary over relatively short periods of time have dials calibrated in

the appropriate units so that they may be quickly set at new values.

The computer, as described, is of the semi-automatic type and the computed information (i.e., the required generation change) is dispatched by means of the teletype channels to the generating stations. The underlying principles are such that they can be conveniently adapted to load the power system automatically on the basis of incremental costs of power delivered in conjunction with recognized forms of load-frequency control.

All of the circuits operate directly from the 115-volt 60-cycle single-phase power supply; the power requirements being in the order of 250 watts. The accuracy of the computer is not affected by voltage or frequency variations normally encountered on electric power systems.

Operating Experience

The computer has fully lived up to all expectations. The PSC are enthusiastic about it because, as the system load changes, it tells them at what plants generation should be increased or decreased and the amount of such change. It gives them the confidence of knowing that they are doing the proper thing at all times.

The savings in production expenses resulting from the co-ordination of incremental production expenses and incremental transmission losses have been estimated at not less than $200,000 per year for the Southern Company System. During the first 4 months the computer was in operation, the severest drought conditions in the past 25 years have been experienced and it has, therefore, been necessary to operate primary fuel plants at full output during the peak-period hours to conserve hydro storages. Therefore, it has not been possible to give recognition to the effect of transmission losses in loading the fuel plants during these hours. However, the computer has been used to the full extent during the off-peak hours and the fuel plants have been loaded for equal incremental cost of power delivered. The PSC have had no difficulty in maintaining the incremental delivered cost of the various units at the same level within ±0.1 mil.

In view of the abnormal hydro conditions prevailing during this period, no studies have been made to determine the actual savings being realized. However, there are several indications that the computer is performing its duties efficiently. For example, prior to the use of this equipment, considerable difficulty was experienced during the morning loading and evening unloading period because of the overloading of transmission lines. When the loading of the plants is determined by the computer for equal incremental cost of power delivered, no difficulty is experienced from this source. This is to be expected since overloaded lines result in abnormal transmission losses. An interesting side light is that a plant on the western end of the system burning natural gas at a cost of 11 cents per 1,000,000 Btu at times operates at the same incremental cost of power delivered as another plant on the eastern end which burns oil costing 35 cents per 1,000,000 Btu; the equalizing factors being that the plant with the low-cost fuel has an incremental heat rate approximately 20 per cent higher than that of the other plant and incremental transmission losses as high as +40 per cent, while the plant burning the high-cost fuel has incremental transmission losses as low so −40 per cent.

Summary

The salient features of the computer are:

1. The computer is compact and requires a comparatively small amount of floor space and is, therefore, suitable for most dispatching offices.

2. The computer is dynamic and the results are based on actual system conditions. Constraints imposed by the system or equipment are automatically taken into account.

3. The computer, as built for the Southern Company System, can be termed semi-automatic, i.e., a large percentage of the data is fed in automatically and the computed information is read out manually. The principles used lend themselves to making the computer completely automatic in its operation.

3. For system studies or setting up future schedules, the computer may be completely divorced from the system. Generation values may then be set up by the hand-set dials, which are provided as part of the computer to determine the effects of different schedules.

4. The power requirements for operation of the computer are quite small, being in the order of 250 watts.

5. The accuracy of the computer is not affected by voltage or frequency variations normally encountered on electric power systems.

6. The values of the *B* constants in the matrix and the intercept and slope values of the incremental rate curves are adjustable over wide limits. Fuel cost dials, calibrated in cents per 1,000,000 Btu, are provided for each station for each type of fuel.

7. Push-button convenience for obtaining scheduling information eliminates human error in calculations and encourages the PSC to load the system for maximum economy of power supply.

Discussion

C. W. Watchorn (Pennsylvania Water & Power Company, Baltimore, Md.): The authors report another splendid achievement toward the ultimate objective of the automatic control of the economical operation of electric power generating systems. Their efforts appear to have been largely directed to attain, as nearly as practicable, maximum economy with respect to the co-ordination of incremental steam generating costs and incremental transmission losses. If the paper is correctly understood with respect to the basis described for the co-ordination of hydro and steam generation, the incremental cost assigned to a particular hydro plant would remain constant until such time when it may be desired either to increase or decrease the amount of water used by that plant over a given period of time. The incremental costs assigned to the hydro plants would then remain constant for long periods of time with the result that, except for the effect of incremental transmission losses, the steam generation would remain constant as long as the system incremental steam cost and the incremental costs assigned to the hydro plants are equal, and the hydro plants would then operate in the peak of the system load, taking all the load variations. It has been shown that such hydro operation can be very uneconomical under certain conditions because of the hydro plant losses that result from the unit, pond, intake, tail-race characteristics, etc.[1] Taking into account the effect of these losses results in less peaked hydro operation than otherwise, just as the inclusion of the effect of the incremental transmission losses, as described in the paper, results in the hydrogeneration being less peaked, but to a much greater extent and independently of such transmission loss co-ordination.

This flattening of the hydrogeneration results in the steam generation participating in or sharing in the system load changes along with the hydro. Such operation results in a variable rather than a constant system incremental steam cost.

Then, since the incremental cost to be

assigned to the hydro plants is equal to the system incremental steam cost as of the same time, it must also be variable. This requirement presents the problem as to a possible basis for such a determination. One such basis, which as of now appears to require considerable simplification if it is to have practical application but which, at least, is a start, is shown by the following equation obtained by rearranging equation 1 of reference 1

$$\frac{dc}{dg_{sh}}=\frac{N}{\dfrac{\dfrac{dL}{dt}}{\dfrac{dq}{dt}}-\dfrac{dg_h}{dq}} \qquad (8)$$

where

$\frac{dc}{dg_{sh}}$ = incremental cost to be assigned to the hydro plant, $ per hour per megawatt

N = incremental water value in $ per hour per 1,000 cubic feet per second and is a constant during the whole of any period of pondage operation of the hydro plant under consideration

$\frac{dL}{dt}$ = time rate of change of the system load, megawatts per hour

$\frac{dq}{dt}$ = time rate of change of the hydro plant discharge, 1,000 cubic feet per second per hour

$\frac{dg_h}{dq}$ = incremental hydro equivalent of the hydro plant, megawatts per 1,000 cubic feet per second. It is a very complicated function that depends on the unit characteristics, the pond, intake and tail-race characteristics, the hydro plant discharge, and the inflow into the pond, all as shown by equation 2 of reference 1.

Any justification there may be for the use of such a basis for co-ordinating hydro and steam generation would, of course, depend on an evaluation of the results obtained with its application as compared with the results obtained with the application of other bases of co-ordinating hydro and steam generation.

1. CO-ORDINATION OF HYDRO AND STEAM GENERATION, C. W. Watchorn. *AIEE Transactions*, vol. 74, pt. III, April 1955, pp. 142–50.

W. H. Osterle (West Penn Power Company, Pittsburgh, Pa.): The authors and the Leeds & Northrup Company are to be congratulated on the pioneering work they have done in the very important field of economic dispatching of generation. On a system as far-flung as the integrated Southern Company System, with high transmission loss and with steam stations having such a range of fuel cost as indicated, it is indeed readily understandable that savings can be made by proper dispatching, including the effect of transmission losses.

A great deal of study is being given to this problem by other companies including my own. Although the savings are not as impressive as those of the authors' company, nevertheless they are real and worth while. The fact that attention is directed to economical plant loading and transmission losses is in itself productive of good results.

I had the pleasure of seeing the computer in operation and was greatly impressed. One fact brought out in the paper was that from the generator information fed into the computer, automatically and manually, it was possible to arrive at a total system load which was metered and shown before the eyes of the operator. As our system has only a total of 1,250 megawatts, it was exciting to see a system total of around 2,900 megawatts.

I would like to ask the authors a couple of questions about the incremental cost curves for the generator units. These are represented, as I understand it, as a straight line with kilowatts as the abscissa and input in 10^6 Btu per kilowatt-hour as the ordinate. The entire curve is multiplied by a factor in proportion to fuel cost. Now the incremental cost of the generating unit is made up of fuel cost plus incremental maintenance, or O.T.F. (other than fuel) as it is usually called. This is generally added at a fixed value expressed in decimal mils per kilowatt-hour. If the curves are drawn on total cost, i.e., fuel plus O.T.F., then the cost multiplier operates on the fuel incremental and on the O.T.F. also. Further, does this one straight line adequately represent the power station incremental cost over the entire range from minimum to maximum? Also, what is done on the loss of a mill or feed water pump? I would appreciate a little further explanation of this important item in economic system loading—how these cost relationships are put into the computer.

E. D. Early, W. E. Phillips, and W. T. Shreve: Mr. Watchorn has advanced what appears to be a very logical evaluation of some of the factors which should enter into the determination of the correct economic loading of hydro plants which are integrated into an electric system which has both hydro and steam stations.

In general, any loss factors which increase with generation will tend to lower the value of generation under a given system condition. Stating the result in another way, the effect will be to reduce peaking of a particular plant. As stated by Mr. Watchorn, superimposing the factors of incremental intake losses, incremental change in tail-race level, etc., on incremental transmission loss will, in general, operate in the same direction as the incremental transmission loss and result in a further leveling of the hydrogeneration.

The measurement and transmission of the necessary data to a computer which could solve Mr. Watchorn's co-ordination equation is quite a formidable problem. Possibly the required simplification as expressed by Mr. Watchorn will remove this objection and the method will then lend itself to solution by means which are economically justified.

Regarding Mr. Osterle's discussion, Southern Company includes incremental supplies, incremental maintenance, and ash-handling expense in incremental generating cost by expressing these costs in cents per 1,000,000 Btu of fuel burned and adding such cost to the fuel cost set on the fuel cost dials. This avoids the error that a change in fuel prices would produce if such costs were reflected in the unit heat curve, referred to by Mr. Osterle. If it is desired to express these costs in terms of kilowatt-hours rather than in terms of fuel burned, a separate dial calibrated in mils per kilowatt-hour could be used.

Southern Company considers that the accuracy of a straight-line incremental heat curve from minimum to normal full load is comparable to the accuracy of the available test and operating data for its units. However, where desired, such incremental cost curves can be represented by two or more straight-line segments having adjustable slopes, with adjustable points of intersection, and adjustable no-load intercept. Discontinuities in such curves can also be represented.

Such factors as loss of a mill or feed water pump, condensing water temperature, boiler and condenser conditions, and the many other variables affecting steam plant operation probably have a greater effect upon maximum loading and average heat rate than they do upon the incremental heat-rate curve; however, to the extent such effects are known, they can be reflected by adjusting the slopes, point of intersection, and zero load intercept of the straight-line segments of the incremental cost computer, or by adjusting fuel price, or both.

Production and Installation of Vertical Water-Wheel Generators

Synopsis: This paper deals with the shop work on Canadian Westinghouse water-wheel generators and with their installation at various hydroelectric stations. The mechanical aspects of such machines are important to the erection as well as in the production operations. The tolerances called for are remarkably close considering the size and weight of the components and the fact that large machines are erected on site. The remarks on design are confined to those concerning components.

THE demand for power in all parts of Canada has doubled each decade since 1910. Mostly the increased load has been taken care of by building hydroelectric stations. The total installed hydroelectric capacity in Canada at September 1, 1954 was 16,000,000 horsepower. The characteristics of the equipment installed depended, of course, on the local conditions, which in no two places were exactly the same. Generators had to be built to suit and data are now available on a wide range of speeds and capacities.

Details of production and erection are described which in practice have been found to be advantageous in installing more than half of the water-wheel generators in Canada. The thrust bearing is the starting point for the mechanical engineer on a generator design and the construction of Kingsbury-type bearings will later be discussed at length. All work in the shops is, of course, planned so each component will be at the site when required by the erectors to meet the construction schedule. First to go are the foundation bolts and details which have to be placed while the forms for the concrete foundation are being built. These are followed by the frame and sole plates, spider and other rotor parts, shaft and thrust bearing, upper and lower brackets, and, finally, the exciters and air casing.

Formerly, the practice was to locate the sole plates individually. Instead, for a number of years past, considerable time has been saved by bolting the sole plates to the generator frame and allowing it to position them for location and elevation. A removable ferrule in the bolt assembly allows for the final centering of the stator. The foundation bolts are, of course, placed in pipe sleeves to permit horizontal adjustment of the sole plates. No paint is applied to surfaces coming in contact with the concrete as bare metal has better adherence.

Stator

The generator frames as now designed and constructed are the result of lengthy experience. Those used in the late 1900's were built up with sections of cast iron. They were superseded by frames of fabricated steel construction. Earlier designs were subject to warpage and cracks which required extra time to correct and added to erection costs.

Modern frames comprise a series of flat, annular, uniformly spaced rings behind the stator punchings. These rings are positioned by vertical plates, structural shapes, and pipe spacers. A steel cover wraps the rings, providing support and controlling the ventilating air. Additional web plates and rings are placed above the stator punchings to support the superstructure of the machine.

Accurate machining of the bore of the stator frame is essential for satisfactory stacking of the punchings; see Fig. 1 Bores are usually held to ±0.005-inch diameter regardless of size. Out of roundness of the bore is held to similar accuracy. The over-all height of the frame is not usually critical; however, parallelism between the top and bottom face of the frame must be held to a tolerance of 0.016 inch.

High-grade silicon steel laminations are used in all large water-wheel-driven generators where efficiency is a consideration. This iron must be accurately punched so that it will build to the correct diameter with smooth faces and slots. Subsequent to punching, the iron is annealed and burr-ground to improve the electrical characteristics and it is coated with an adequate insulating material. Two coats of sodium silicate are used as it is one of the most permanent and fire resistant types of coating available. The fingers of the iron are supported by finger plates. To prevent vibration of the iron in the slot portion, it is essential that the finger plates provide adequate support to the iron. For this purpose the use of nonmagnetic rolled steel fingers held to a heavy steel punching by spot welding has been standardized. This construction provides the maximum mechanical reliability without increasing the core loss in the generator. Vent finger plates spaced at regular intervals in the stator core are of similar construction to the end plates except that the fingerlike spacers are a much smaller nonmagnetic steel section.

After the punchings are stacked in the frame and compressed or "pulled down," Fig. 2, the through bolts are welded to the frame, top and bottom and at each intermediate frame ring, to tie the iron core securely to the stator frame. The ends of the stator slots are dressed off to remove sharp edges which might damage the coil insulation during winding. Gauging of the slots assures that the coils will fit the slots. The stator bore is checked for roundness and dimensions to make certain that it is within the required tolerance. It is normal practice to allow the stator bore measurements to average from size on to +0.030 inch with a maximum variation from the average of ±0.020 inch. However, other electrical considerations for the air-gap design often affect these tolerances.

Experience indicates one and sometimes two coil support rings are necessary to prevent movement of coil ends under short-circuit conditions. These must be accurately located so that the coil does not have to be distorted or pulled back excessively to come up against the rings. For this purpose, the rings are located by an accurate gauge which is positioned relative to the slot and has exactly the same kick as the coils. This procedure allows installing coils without undue straining which could shorten the coil life. Furthermore, coils are inspected for shape on a master gauge which assures that any spares will also fit the slots and support rings. Installation of coils or "winding" is shown in Fig. 3.

Coils and slot manufacturing tolerances are such that there is no possibility of having a tight coil that cannot be inserted in the slot. It is essential, however, that the final clearance be less than 10 mils to prevent vibration of the coil in the slot. This is accomplished by wedging

Paper 55-162, recommended by the AIEE Power Generation Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N.Y., January 31–February 4, 1955. Manuscript submitted October 18, 1954; made available for printing December 2, 1954.

W. D. HOUSER, W. HINDLE, and J. A. TYERMAN are with the Canadian Westinghouse Company, Ltd., Hamilton, Ont., Canada.

Fig. 1. 50,000-kva generator frame on a 36-foot horizontal boring mill. The openings around the frame are for mounting the air coolers

Fig. 3. Winding of the coils in the stator is one of the longest assembly operations whether in the shop, as shown, or in the field. The long leads projecting from the top of the coils eliminate individual group and series connectors

the side of the coil with a mica or a semiconducting plastic sheet. This sheet is supplied in a range of sizes from 0.010 to 0.025 inch to accommodate the tolerance range allowed.

Since 1942 it has been the practice of the Canadian Westinghouse Company to braze all connections on the armature winding including series, group, and parallel rings with a silver-phosphorus alloy. This procedure eliminates the uncertainty of soldered connections and reduces the number of connections by one-half. Slot wedges are made from cloth-base micarta strips principally because of their strength, uniformity, and dimensional stability. These wedges are notched opposite the ventilating ducts to facilitate a streamline flow of air through the duct. Depending on customer preference, the stator may be either stacked and wound in sections, in the factory, or in a complete circle in the field. In many cases it is preferable to stack and wind in the factory to reduce the assembly time and the usual congestion in the powerhouse.

In the event that the stator arrives on the job in stacked and wound sections, it is set up to correct elevation and centered, sole plates are grouted and the coils bridging the splits between sections are made up to complete the winding. This is a time when great care must be taken as stator winding should only be attempted by experienced workmen under expert supervision. The winding personnel are supplied with special rubber mallets, wedge drivers, side-mica drivers, and pullers as well as all the necessary winding information from the design engineers. Where coils are to be heated during winding (continuous taped asphalt bonded type), brazing transformers with special connectors are available.

The number of coils lifted during the closing of a split depends on a number of factors and should be determined for each particular winding. Some of the factors involved are:

1. Type of coil, i.e., mica folium, continuous taped asphalt bonded, or Thermalastic.
2. Depth of slots.
3. Throw of coils.
4. Frame size.
5. Voltage class.

The number may vary from three to six times the number of coils in the throw. The risk of possible coil damage is great if less than the recommended number of coils are lifted while a larger lift than necessary results in increased cost, time, and disturbed coils. After the coils are placed in the slots and before connecting, they are given a momentary high-potential test 1.25 times final test voltage. After connection, and before the rotor is placed in the stator, the winding is given a momentary high potential of 1.15 times final test voltage. These potential tests may be made with either alternating voltage, or the equivalent direct voltage. Each coil is tightened in its slot, as mentioned previously, based on individual measurement. Contact resistance tests with an ohmmeter check this operation.

When the complete stacking and winding is to be done at the site, the frame is set up, if possible, in its final location on the generator foundations with stacking and winding operations being carried out in position. On occasion it may be necessary to stack and wind in the erection bay, in which case the complete wound and stacked stator is moved as a unit to the generator foundations and is set to correct elevation and centered. To provide additional strength, on conventional machines, the upper bracket is usually mounted temporarily on the stator before the lift is made.

The elevations and center may be set by the turbine-shaft coupling location,

Fig. 2. Partially stacked 106,000-kva frame showing the pressing operation which is carried out for every 12 inches of iron added. The 25-ton jacks bear down on temporary pressing plates. The stator tie bolts are visible between the jacks; guide strips maintain slot alignment

when available. A piano wire plumb line with a 100-pound lead weight damped in a pail of heavy oil is suspended from the top of the stator frame. Its exact location is determined either from permanent reference plugs set in the foundations or from the turbine-shaft center. The stator frames are centered to ±0.032 inch and to level within 0.004 inch. Engineer levels, micrometer targets, and pin gauges are used. The stator is now dowelled to the sole plates.

Rotor

The rotor transmits the torque from the shaft to the field poles and consists of a spider, rim, poles, blowers, and other miscellaneous parts. The rotors fall into two general classifications:

1. Umbrella design; see Fig. 4(A).
2. Conventional design; see Fig. 4(B).

The umbrella design is usually applicable to large-diameter slow-speed machines, while the conventional design is usually confined to high-speed generators. The umbrella design provides manufacturing economies as well as reduced installation costs at the powerhouse. The rotor can be lifted separately from the shaft; see Fig. 5. Thus crane capacity is reduced by the weight of the shaft, which in the case illustrated amounted to 10 per cent of the weight of the rotor. An umbrella installation also reduces the powerhouse building costs by lowering the crane rail height required for dismantling a generator.

The bearing support bracket for the umbrella-type unit is less expensive than the supporting bracket for conventional units. Since the span of the bracket is reduced and since the stator frame does not have to support any vertical thrust from the rotor, there are further design economies.

Today spiders are either fabricated or built up of disks of plate steel. For fabricated spiders, generally only the hub section is built up from annular rings of heavy plate steel. Arms of I-beam or box sections are welded to the hub. At the ends of the arms there is a heavy post to take the "shrink" and "torque" keys, which hold the rim on the spider. After fabrication, this section is stress-relieved to assure that the dimensional accuracy of the machine will be maintained and to eliminate any danger of operating failure from residual stresses. The spider is machined on a boring mill to tolerances of 0.003 inch on the bore and 0.005 inch on the arms.

In designs where it is impossible to use the laminated rim construction because of small diameters or high centrifugal forces, the plate type of rotor is used. A noninterconnected stack of completely machined disks is used. These disks are shrunk on the shaft as an accurately machined assembly. The poles are attached directly to the plates by dovetail slots in the outer edges.

The fabricated spider involves an outer rim. The function of this rim is to contain the centrifugal force of the poles during operation and to provide a flux path between poles. A staggered assembly of sheet steel segments is used. These segments act as a link structure so that the segments are in tension with the forces transmitted to the next segment by means of the through bolts acting as shear pins. Consequently, no reliance is placed on frictional forces to hold the rim punchings when rotating.

The rim punchings must build up in a circle of sufficient accuracy to have no appreciable affect on the air gap. This frequently requires an accuracy in the rim punching segment to within 0.002 inch. Such accuracy is achieved by a compound die without any resort to indexing and its resultant inaccuracies.

In building the rim, Fig. 6, the lower end plates are set up in correct location on the spider and are supported from the floor. Temporary building keys are

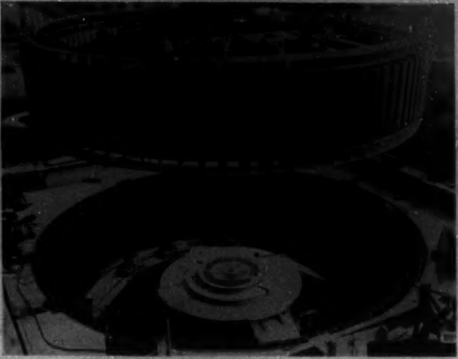

Fig. 5. The umbrella-type rotor shown ready for lowering into the stator is complete with rim and field poles, top and bottom blowers. Already installed in the lower bracket are the thrust bearing and shaft. Also visible are the hydraulic brakes sitting on the bracket arms

placed in the spider arm dovetails. As the laminations may vary slightly in thickness within the tolerances of the steel suppliers, every effort is taken to ensure proper distribution of each box of punchings so that the rim thickness will build up evenly. Stacking is carried out with the aid of accurately machined building pins. The laminations are pressed after every section of approximately 12 inches has been stacked. These methods ensure a tight, compact rim of accurate diameter. Permanent rim studs are inserted and tightened to a predetermined tension.

After the rim has been stacked the temporary dovetail keys are removed and the rim is heated by electric space heaters for the insertion of the permanent torque keys. The amount of interference is such that at moderate overspeed the rim remains tight on the spider but, at maximum overspeed, the centrifugal forces overcome the interference forces. Before the rim has cooled, the permanent rim stud nuts are checked for tightness with a torque wrench to ensure that all studs are under the correct tension. When cool, the nuts are welded top and bottom.

The field poles carry the magnetic flux generated by the field coils and mechanically position the field coils. These poles are made up of sheet steel laminations, clamped together by end plates, and riveted together. Between the pole body and the rim is a dovetail joint designed to withstand the stresses at overspeeds and to prevent any relative movement of punchings. The poles are wedged tight into the rim by the tapered dovetail keys. These poles can be easily removed, if necessary for maintenance, by removing the dovetail keys with a special puller. For ease in fitting, the dovetail keys are tinned all over and hardened on each end for driving.

First the poles alone are tried and the dovetail keys are inserted and marked. The field coils are then slipped on to the poles and these assemblies are mounted. Considerable care is taken to ensure that the field coils are tight. The pole and coil assemblies are individually weighed before shipment to facilitate weight distribution around the rotor as this minimizes balancing problems.

Shaft

The generator shaft functions to transmit the torque from the water wheel to the rotor and to support the rotating members. This shaft is made from a carbon steel forging which has been heat-treated to make a homogeneous metallurgical structure free from forging and casting stresses. It is turned and polished all over to reduce stress concentration to a minimum. Essential areas such as come in contact with other members are accurately machined and ground to ensure the satisfactory alignment of the unit. Shafts of this nature are liberally proportioned so that stresses are low and conditions of critical speeds and magnetic pull are satisfied.

The thrust collar is a continuous part of the shaft forging for umbrella-type machines; see Fig. 7. On conventional units, when a separate thrust collar is required, the collar is assembled with a light interference fit to assure accuracy of alignment and to prevent movement and fretting corrosion. The outside diameter of the thrust collar face is machined to runout of less than 0.0002 inch. The runout on the ground surfaces is also held to 0.0005 inch.

For a conventional unit the shaft is positioned vertically through the floor opening in the erecting bay of the powerhouse and is blocked at a suitable eleva-

tion. The shaft at the spider fit and the hub bore of the spider are cleaned and checked for burrs or other imperfections and the fit dimensions are carefully measured as a check on the interference provided. The hub is expanded by use of space heaters to a predetermined clearance of the bore. The hub bore and shaft fits are brushed with light machine oil or a solution of molydenum disulphide and the hub is lowered down over the shaft with the use of the powerhouse crane until it is correctly positioned with the bottom against the shoulder on the shaft. Accelerated cooling on the bottom of the hub contracts this part of the hub on to the shaft first and prevents the spider from pulling away from the shoulder as it cools.

On occasion, the hub may be expanded while in a position around the shaft above the fit, with the shaft being pulled up by the crane to the correct location. This method is used where the spider is of the plate type. The shaft-lifting device provided must be suitable for lifting the total weight of shaft and spider. With the umbrella-type rotor it is not necessary to stack the rim over a pit as the shaft is not connected to the spider during this operation. Hence, the spider may be set up anywhere in the powerhouse where suitable space and permissible floor loading is available.

Brackets

The function of the main bracket is to support the weight of the rotating members through the thrust bearing and maintain alignment through the guide bearings mounted thereon. The bracket consists of a fabricated hub section which serves as the oil pot and bearing support. This hub is usually supported by four to eight radial arms which transmit the forces to the foundations. The deflection of these brackets under load must be held within limits which will assure clearances in water-wheel parts and exciters in the order of 0.10 inch.

All oil tight welds are designed with welds on both sides, each of which are checked for oil tightness. After fabrication the bracket parts are stress-relieved by heat treatment. The lower bracket is assembled in the erecting bay, placed in position and accurately centered within ±0.010 inch, and leveled to within 0.0005 inch per foot of span. Dowelling to the grouted lower bracket sole plates completes this operation. The upper bracket is centered and leveled to similar accuracy and dowelled in position to the frame prior to final assembly and then removed until the rotor is in place.

Thrust and Guide Bearing

As stated previously, the thrust bearing is the heart of the mechanical design. The Kingsbury-type bearing design, Figs. 8 and 9, has been further refined since 1948 because of new babbitting techniques, improved oil cooling and circulation, improved manufacturing practices, and metallurgical developments. The modern bearing is simple to install and adjust, reliable in service, and easy to maintain.

Bonding of babbitt to the individual bearing shoes has struck a serious obstacle in the blistering of the babbitt face by hydrogen released from the steel shoe. To circumvent this hazard, the "no bond" practice has been adopted where the babbitt is held mechanically to the steel by a network of dovetail slots. Operating experience is now proving this practice sound.

A viscosity pump designed into the trailing edge of the thrust bearing provides a unique improvement in the oil circulation. This arrangement gathers the hot oil from the trailing edge and discharges it directly into the area of the finned copper cooling coil. Without it, hot oil is picked up by the next shoe. This viscosity pump along with carefully placed baffles and liberal passages have all improved the circulation within the bearing oil pot. Foaming from turbulence at the top of the oil pot is controlled by a baffle and weir construction in conjunction with a viscosity pump built into the guide bearing; see Fig. 8. Air in the bearing oil film means increased kilowatt losses and higher bearing temperatures.

The runner plate is made from gray cast iron with chilled rubbing faces. Addition of nickel in the iron results in a close grain structure that can be lapped to a high polish. The oil absorbed in the microscopic pores of the cast iron and the flake graphite in the iron act as a solid lubricant in starting, prior to the establishment of the oil film.

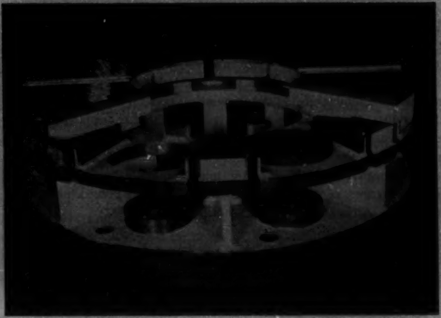

Fig. 9 (above). A 56-inch thrust bearing with two shoes and one jack screw and shoe support removed

Fig. 10 (right). Des Joachims Generating Station on the Ottawa River consisting of eight 50,000-kva 106-rpm conventional-type generators with cooling air recirculated through air-to-water coolers mounted on the frame

For the thrust bearing to give the most efficient and satisfactory service, it is imperative that the utmost care is taken in the cleaning and handling of the components during installation. The assembly must be done under proper working conditions in a clean atmosphere free from abrasive dust or dirt.

With the rotor placed in position, supported by the brakes, the upper bracket is installed and the thrust bearing base ring complete with jack screws and shoe supports already assembled is placed in its proper location in the oil pot. The bearing shoes are assembled on the shoe supports and lightly brushed with a graphite grease after which the runner plate is placed on the shoes. The thrust collar is pressed on the shaft using a pressing plate and pressing bolts. The fits are lightly coated with molybdenum disulphide to prevent galling. The circular key is inserted and the runner plate is fastened to the thrust collar. Proper load adjustment on the shoes and jack screws is now obtained through the use of strain gauges permanently located in the jack screws; these gauges may usually be adjusted within ±2$^1/_2$ per cent. For machines ordered without strain gauges, the "slugging arc" or other methods are used for adjusting the load.

The modern guide bearing has multiple, individual shoes. Separate adjustment on each shoe makes alignment easier and more accurate than with the ring-type guide bearing. Maintenance or replacement is simplified and bearing losses lowered. The individual shoe is generally set for a clearance of 0.010 inch from the journal, which is ample allowance for thermal expansion. It is usually possible to combine one guide bearing into the thrust bearing assembly. Here the periphery of the runner plate acts as the journal for the guide bearing.

Exciters

For the last number of years, direct connected exciters have been specified. One effective manner of reducing the over-all height was to use a telescopic construction in which the pilot exciter is located partially within the main exciter commutator. The armature winding of the exciter is electrically balanced to reduce the effect of unbalanced magnetic pull.

Exciters are tested in the shop where brush neutral, compensation, etc., are set to eliminate field adjustments. New designs are given a heat run and all designs are checked for ability to meet the specifications. Until recently the exciter system has taken the form of main and pilot exciters. In cases where the magnetic amplifier type of voltage regulator is specified, the direct connected pilot exciter is entirely eliminated.

General Features

Most users today prefer an enclosed ventilation system. Centrifugal blowers mounted on the rotor force the air through the core of the machine and through the air-to-water coolers on totally enclosed generators. All air passages in the machine have been improved to increase the air circulation and, in recent years, this has included new stator wedge and new vent duct designs. Air turns and splitters are put in at advantageous points to direct the air with a minimum drop in pressure. To eliminate hot spots, air coolers are arranged around the frame of the generator. These coolers are designed so that there is no possibility of air locks in the water tubes which in the past have caused considerable loss in cooling capacity.

The spider of an umbrella-type generator is connected to the top of the shaft with a circle of hollow dowels which have a light interference fit in both shaft and spider. Bolts inside the hollow dowel hold the assembly together. During assembly these dowel holes are reamed after the rotor is lowered onto the shaft. At this time, the weight of the rotor is actually carried on the brakes, with the safety blocks in place. Suitable fixtures are supplied for the rapid insertion or the removal of these dowels. It is possible to have such a rotor out for repair 4 hours after the generator is shut down.

In the umbrella machine the unit is provided with a thrust bearing lowering device. The device consists of three power-driven screws, the running nuts of which attach to and lower the thrust bearing assembly. In the lowered position, all parts are accessible for inspection and parts can be removed with a trolley supplied with the unit. On umbrella units designed for outdoor service, it is possible to remove armature coils and field poles for maintenance without opening the air casing or using overhead cranes. The field poles are removed by means of a monorail and chain block. Keys in the field pole dovetails are removed by means of a special puller.

The generator field circuit breaker is now often mounted on the upper bracket in close proximity to the exciter. This saves considerably in installation costs and dismantling of a unit as it is not necessary to disconnect heavy current-carrying field leads. The upper bracket, field circuit breaker, and exciter frames come off as a unit.

Alignment

In the umbrella installation the alignment is simplified because of the elimination of one of the guide bearings. In general, the shaft lengths are shorter which results in less throw because of the manufacturing tolerances necessary. The guide bearing located with the thrust bearing is adjustable to allow for final alignment later.

To retain permanent alignment records, it is becoming more common to work from permanent reference plugs, which are inserted while the concrete foundation is being placed. Once the shaft is in position, it is necessary to work from either the turbine shaft or the pit wall reference plugs. For alignment purposes, the generator shaft must hang freely from the thrust bearing, with the lower guide bearing left out.

The generator shaft coupling is located vertically at an elevation slightly below operating position, as it is important that any adjustment of the thrust bearing jack screws be done in a load-increasing, or upward, direction. Preliminary shaft alignment is carried out by adjustment of bearing jack screws until the coupling flanges are parallel within 0.15 mil and the flanges are in the same vertical plane.

Several upper guide bearing shoes are now tightened to prevent horizontal movement of the rotor. The rotor is rotated 360 degrees to distribute evenly the lubricant between the shoes and runner plate. The coupling flanges and the upper guide bearing journal are checked and the readings recorded. The rotor is then rotated 180, 360, and 540 degrees, with readings being checked and recorded at each position.

The shaft runout at the coupling flange should not exceed 0.00025 inch per foot of shaft from runner plate to coupling, and the out-of-parallelism between coupling flanges should not exceed 0.00003 inch per inch of coupling flange diameter at every check position. The guide bearing shoes are now removed and the final alignment and load adjustments are made. The coupling is now made up and the whole rotating assembly is checked. Once the alignment has been approved, final assembly to running clearances of the guide bearings is carried out. All bearings must be cleaned and flushed out to remove all possible foreign matter.

Dryout

The dryout of the windings depends on the insulation resistance readings, type of coil, and the urgency of the work. It is considered that, if the unit is urgently required for production of power, dryout may be omitted if stator winding insulation resistance to ground, per phase, is in the order of 75 to 100 megohms. However, if time permits, it is always good insurance to carry out the dryout until resistance readings become consistent for 48 hours, at a constant or corrected ambient temperature. A running dryout with stator windings short-circuited, is recommended.

The temperature should be brought up gradually but not in excess of 80 degrees centigrade, as measured by stator coil temperature detectors. Megger readings per phase should be taken at regular intervals and plotted on a graph. After the winding is dry, the generator may be given the final overpotential test, either a-c or d-c, at AIEE test standards[1] and placed on load.

Balancing

Although every precaution is taken in design, fabrication, and assembly to distribute the weight properly, once the machine is started up dynamic unbalance may be present. On higher speed machines, over 150 rpm, considerable success has been obtained by use of a portable dynamic balancer.

The low-speed machines are balanced by adding the necessary weight or weights by the vector analysis method, assisted by dial indicators. The shaft is painted with a thin coat of white wash in an accessible location near each guide bearing. Thousandths dial indicators are mounted to indicate the shaft at these spots. The unit is given an initial run and the throw is marked on the whitewash with a lead pencil or scribe. The indicator variations are recorded. On stopping, the high point of the throw is recorded in degrees from a reference plane. A trial weight is then applied at random and the trial run made and recorded. By vector analysis the initial unbalance is calculated and subsequently corrected by a balance weight placed directly opposite. The balancing operation may be repeated to refine the balance. On occasion, this procedure may require expanding into 2-plane balancing when dynamic unbalance is present.

General Remarks on Field Installation

Erection in the field is a continuation of factory manufacture and assembly. The large size of the machines prevents shipment as a completed unit. Engineering design and factory operations aim at reducing field work where possible, because limitations in facilities at the job site are the rule rather than the exception.

For economical and efficient erection a number of factors must be considered for each particular installation:

1. Delivery schedule of component parts: a proper sequence of shipment must be followed.
2. Manpower available: a basic crew of skilled workmen and supervisors with sufficient helpers is required.
3. Powerhouse conditions: sufficient working and storage areas are desirable as congestion makes for an inefficient operation. Cranes, compressed air, and construction power must also be available as required.
4. Overtime and shift work, while reducing erecting time, do not do so in direct ratio because of loss in efficiency. Realistic in-service dates should be laid down, as a month extra at the installation time may well result in months or years of extra life from the machine.
5. Erection equipment supplies must be adequate both from efficiency and safety standpoints, and must be of sufficient quantity for the job at hand.

Conclusion

It is safe to say that present-day designs for hydroelectric generators are a combination of improvements aimed solely at better output performance and at overcoming former operating inconveniences as well as facilitating assembly and maintenance. These latter improvements are almost entirely mechanical and are the natural outcome of years of experience on the part of both the design engineers and the operating engineers and personnel. Accurate manufacturing to close tolerances make the components for 400-ton generators as completely interchangeable as those for a washing machine motor.

The operators of expensive pieces of apparatus such as water-wheel generators are not backward in advising the manufacturer of what they consider shortcomings in any particular generator. If the shortcoming cannot be corrected in the generator in question, then at least the designer must overcome it in future designs.

As "down time" for maintenance often means a loss of potential revenue to the operator, generators that remain trouble-free mechanically save significant money each year. However, it is certain that no operator today would order a water-wheel generator expecting never to have to dismantle it for overhaul. Therefore, it is a further saving to this operator if he know that when such an overhaul comes up his machine will come apart and be able to be reassembled easily and accurately. These are goals towards which the design engineer and shop workman strive continually. No one would be satisfied today with a new machine built to 1930 design standards. Greatly improved designs are available today in generators, and more rigid and exacting purchase specifications are an indication that operators are well aware of the type of machine that is now available. The generator designer continually strives not only to keep abreast but to keep ahead of the buyers' specifications, and will be likely to continue to do so as long as we remain under the free enterprise system.

Discussion

F. H. Duffy (Aluminum Company of Canada, Ltd., Shipshaw, Que., Canada): The authors have done an excellent job of outlining the design and erection procedures of one manufacturer. It would be most interesting to hear from other manufacturers as to whether the same procedures are used.

One cannot help but be impressed with the close design tolerances maintained. In the industry it is often taken for granted, but the watchmaker type of work required is certainly worthy of emphasis.

Where direct current is used for test purposes it is assumed that the AIEE recommended ratio[1] is used.

Some elaboration on the use of the strain gauges for thrust bearing adjustments and the method of computing the $2^{1}/_{2}$-per-cent error in adjustment would certainly be of interest to operating personnel. When speaking of ease of assembly and fit of spare parts, it should be noted that any time the machine is dismantled or when there is a thrust bearing failure the same adjustment procedure must be followed. It might also be noted that in the erection of the unit, the trueness of the water-wheel erection has a definite effect on the ease of alignment.

Since the generator winding has been tested with high voltage and since short-circuit dryout uses about full load current, it would certainly seem more efficacious to eliminate the dryout period and generate useful kilowatt-hours by operating at slightly reduced voltage and load for the ordinary dryout time. It is probable that dielectric absorption tests are more indicative of the winding condition than any number of megger readings and these tests are easily made if a fairly high-voltage d-c test set is available.

REFERENCE

1. ALTERNATING AND DIRECT VOLTAGE ENDURANCE STUDIES ON MICA INSULATION FOR ELECTRIC MACHINERY, **Graham Lee Moses**. *AIEE Transactions*, vol. 70, pt. I, 1951, pp. 763-69. (Ratio 1.6 recommended.)

H. F. Abbott (Quebec Hydro-Electric Commission, Montreal, Que., Canada): The extent to which the authors have covered the subject of the paper, in the length permitted, is worthy of tribute. However, I have a few questions to ask, and statements to question.

BEARING CLEARANCES RELATIVE TO RUNOUT

It seems general to provide as much as 20 mils of diametral clearance for guide bearings on large generators; yet we are concerned if the machine operates with 5 thousandths shaft throw. When there is 5 thousandths shaft throw, the oil film thickness, instead of being 10 thousandths uniformly around the shaft, is momentarily $7^{1}/_{2}$ mils on one side and $12^{1}/_{2}$ mils on the other side. It would appear that the reaction exerted by an oil film as thick as $7^{1}/_{2}$ must be very small; moreover, the difference in reaction created by the oil film on one side, being such a small percentage different than on the other side, cannot provide any considerable balancing force.

Is it not true, therefore, that normally the guide bearings provide little restraint against shaft throw? Is it not the case that when a machine shaft runs smoothly without appreciable throw, that it is either because eccentric forces—centrifugal, mechanical, hydraulic side thrust, and electromagnetic—have been reduced to near zero and the throwout is independent of guide bearing restraint, or because an unbalanced electromagnetic force from the stator or hydraulic force on the turbine holds the shaft towards one side of the guide bearings so that the necessary restraint is developed to result in little throw to the shaft?

TOLERANCES

Our experience has been that machining tolerances are usually much greater than those indicated in the paper. We would also point out that it is difficult to measure ±5 mils on a 40-foot diameter stator bore.

BALANCING

I would like to inquire why the trial weight should be placed at random after the high spot is known? Why not opposite the high point to avoid the angular relation of vectors? Also should not the dynamic balance be checked at two widely separated speeds to confirm whether the counterweight is the right distance from the center to give true dynamic balance at all speeds including the overspeed condition?

DRYOUT

I would like to see the statement "temperature should be brought up gradually," qualified approximately by specific figures. The period allowed for raising temperature varies widely between manufacturers.

On the final overpotential test we do not agree that direct current is acceptable. We believe that, if the AIEE standard is revised to include direct current some further qualification would have to be coupled to the d-c test such as leakage current, or shape of the curve of leakage current versus voltage under a specified rate of build-up. We have had instances where new generators did not come near to passing the standard a-c high-potential test and they had to be completely reinsulated, although a previous d-c test, which we had been urged to accept had been carried out successfully.

VENTILATON

I would suggest that particular stress be placed on the improved distribution in the air circulation improvements made in recent years.

F. L. Lawton (Aluminium Laboratories Ltd., Montreal, Que., Canada): The authors are to be congratulated on a distinct contribution to the literature on fabrication and erection aspects of vertical hydroelectric generators. The literature is, in fact, notably lacking and hence the paper is most welcome. It is to be hoped other manufacturers will contribute papers of this type in the future, as it will then become possible to place the erection of vertical water-wheel generators on that sound engineering basis so essential to optimum performance over a long service life.

The information given in the paper on dimensional tolerances is valuable. The authors make the statement "It is essential however that the final clearance be less than 10 mils to prevent vibration of the coil in the slot." It would be most helpful if the authors would indicate, to the extent information is available, the effect of limiting such clearance to, say, 5 mils.

Referring to the rotor rim, the statement is made that "The amount of interference is such that at moderate overspeed the rim remains tight on the spider, but at maximum overspeed the centrifugal forces overcome the interference forces." Do the authors know of cases where the rim has moved on the spider?

The use of strain gauges permanently located in the jack screws of the thrust bearing is a distinct step forward, as it should enable the determination of hydraulic thrust caused by the turbine runner more easily than has been the case in the past.

The authors state "Preliminary shaft alignment is carried out by adjustment of bearing jack screws until the coupling flanges are parallel within 0.15 mil and the flanges are in the same vertical plane." Should this not be horizontal plane? Are the dimensional tolerances for shaft runout at the coupling flanges and for out-of-parallelism between coupling flanges maximum values or do some customers specify closer tolerances?

What is the authors' experience as to the most effective way of minimizing adjustments after units have been installed for a few years when, in some cases, it is found that there has been a drop in elevation or settlement of the powerhouse structure on the downstream side?

K. R. Knights (The Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada): This paper is written on a subject that is of widespread interest. We are most interested in those machine tolerances that directly affect the results of the rotational alignment erection test. Our standard field alignment tolerance, as given in the following is not more stringent than that specified in the paper except that it provides limits on the coupled generator and turbine shafts: "The overall field alignment of the coupled generator and turbine shafts as determined from a rotational test—shall be such that the centre of each or either shaft shall not deviate from the true theoretical axis more than 0.00025 inch multiplied by the distance in feet from the thrust bearing rubbing surface to the point of measurement. In addition, the true theoretical axis of the coupled shaft shall not deviate from the plumb more than an amount calculated in the same manner."

To ensure that the foregoing alignment requirements are obtained with a minimum of field delay and for other reasons, it has been found desirable to have the thrust collar provide a light interference fit on the shaft, as noted in the paper, and to have the upper and lower surfaces of the thrust collar and runner plate faced true to the bore (shall not have a rotational error as measured by a dial indicator) within a tolerance such that the cumulative error of the two surfaces shall not exceed 0.001 inch. The shaft runout and the shaft coupling contact face are also held to acceptable tolerances for this purpose.

Jack screw strain gauges have been found to provide an accurate means of distributing the load between shoes. In addition, they have been utilized to make direct measurements of hydraulic thrust. Use of these gauges is much facilitated if the leads are extended down from the upper bracket. Design of the machine, however, should permit use of the "slugging arc" method of alignment so as not to be entirely dependent on devices for this important operation; a few strain gauges have failed in service.

The practice of accurately forming coils during manufacture so as to eliminate undue strain when tying and connecting them in place is considered to be in the interest of the purchaser. It is felt that coil insulation should only be disturbed where absolutely essential, as in the closing of splits.

Thermalastic insulated windings with full coils now have been purchased for a number of large, medium-speed water-wheel generators. As noted in the paper, the splits were closed successfully by lifting approximately six times the number of coils in a throw, in view of the comparative rigidity of this type of insulation.

It is stated in the paper that the upper bracket is mounted temporarily on the stator before a lift is made. On an umbrella machine, with a light upper bracket, the question arises as to what provision is made for lifting a complete stator.

Large, single guide bearing generators have always been purchased with the following stipulation, which is meant to provide assurance of entirely stable operation under all conditions of operation and test: "The design of the generator shall be such that it will have adequate mechanical stability to operate successfully under all overspeed and fault conditions which may be experienced during operation. This requirement shall apply with the generator either coupled to or uncoupled from the turbine."

With respect to the authors' comments on stator lamination insulating material, it would be of interest to hear their views on the relative merits of sodium silicate and high temperature baked on enamel from all viewpoints, particularly with respect to moisture resistance.

Our Kingsbury thrust bearings of the original Kingsbury design have a good operating record on our system. A number of machines supplied within a recent 2-year period, however, were equipped with shoes of the thick slab type and experience with this major variation from the original Kingsbury design has not been so successful. As a result of this experience, we are in agreement with the present practice of not only eliminating the babbit bond as noted in the paper but also supplying all shoes along the lines of the original undercut design.

W. D. Houser, W. Hindle, and J. A. Tyerman: The authors wish to thank the several discussers of this paper and take this opportunity for replying to some of the points raised.

The advantages of sodium silicate or water glass over baked-on enamel or varnish as an insulation on stator laminations are that it: 1. has a thinner film for equal insulation which enhances a better stacking factor; 2. has a slower rate of deterioration; 3. is more resilient; 4. withstands higher temperature such as might occur in a stator fire; and 5. withstands higher stacking pressures as it is an inorganic inert material.

Some manufacturers are known to design rims that are loose at all speeds but are suitably restrained so that only uniform radial expansion is allowed.

We agree with Mr. Duffy that elaboration on the use of strain gauges for thrust bearing adjustment would be of interest to operating personnel, and it could well be the subject of a further paper. When reassembling a machine after overhaul, no adjustment is required if the old shoes are reused. Minor adjustment is sometimes required with new shoes because of slight manufacturing tolerances between individual shoes. With regard to strain gauge failures, we have found that improvements in the termination of the leads from the load cell have reduced the number of failures to a very low percentage. Further improvements can be expected to reduce this almost to the vanishing point.

In the case of installations that have suffered foundation settlement, shaft misalignment can usually be compensated for by adjustment of the guide and thrust bearings as they are both of the pivoted type. The settlement would have to be very severe before it would require a releveling of the stator frame.

To clear up any misunderstanding over the tolerance given in the paper for stator bore, we would like to make it clear that this refers only to the bore of the frame itself. We agree that it is not possible to hold the bore of the stacked core to tolerances of ±0.005 inch in diameter. The gauges used for measurement of large bores to the accuracies indicated are quite practical and are in daily use in our shops. The dimensional tolerances given in the paper are actually closer than that required by any known purchase specification to date and are giving satisfactory results in the field.

In designing the coil and slot sizes, the designer chooses dimensions that will result on the average in 15-mil clearance. With side mica strips available in 10-, 15-, 20-, and 25-mil thicknesses, it is possible to achieve a final clearance of not greater than 10 mils and averaging 5 mils. A small clearance is considered necessary to prevent tape migration caused by the thermal movement of the copper conductors, which can occur when the tape is prevented from moving with the copper.

Direct voltage testing has been extensively used by our field erectors for several years now, using up-to-date d-c to a-c ratios as developed by the AIEE subcommittee studying this subject. While we have had very few occasions to doubt the validity of such d-c testing, we do feel that the higher ratio now recommended by the subcommittee is a step in the right direction.

For asphalt and earlier types of coils, it is highly desirable to drive out contained moisture and solvents very slowly to avoid mechanical damage from vapour pressures. In general, the stator temperature for dryout is brought up to 80 degrees centigrade at a uniform rate over a 24-hour period.

We agree with Mr. Abbott that an oil film of 10-mil thickness will do little to restrain a shaft throw of 5 mils, but it must be realized that the clearance will be less than 10 mils at operating temperatures. However we feel that shaft throw does not originate in the guide bearing, and any serious throw should be overcome at the source, if possible, rather than call upon the guide bearing to restrain it. Guide bearings to restrain any considerable radial forces would then have to be much bulkier and more expensive than those commonly in use today.

Dynamic balancing of vertical water-wheel generators is of considerable importance and a complete explanation is too lengthy for this paper. It too could well be the subject of a separate paper.

Symposium: How Can the Utilities Best Make Use of Modern Science?

Implementation of a Research Program for the Electric Utility Industry

J. E. HOBSON
FELLOW AIEE

W. A. LEWIS
FELLOW AIEE

M. S. OLDACRE
FELLOW AIEE

IN January 1954 a paper[1] which stressed the needs of the electric utility industry for an expanded program of research was presented. This theme was expanded and supplemented in a similar paper.[2] The objective of this third paper is to summarize the comments received on the first two and to make further suggestions for a research program for the electric utility industry.

Comments on Previous Papers

The first papers were followed up by many discussions with utility executives and engineers, college faculty members and students, financiers, economists, and leaders of other industries. An extremely wide range of views was found. There was majority but decidedly not unanimous, agreement that more extensive research programs are desirable, which will investigate basic problems of the industry and provide for its long-range needs. Some utility executives were inclined to leave the job of research and development entirely to equipment manufacturers, being satisfied with whatever technical progress is offered to them. Some believed that the role of the utility companies in research should be confined to encouraging and co-operating with the manufacturers by proving and testing manufacturers' research results. Others were distressed by the duplication of efforts, facilities, and investments necessary when similar and parallel research and development programs are carried on independently by several manufacturers.

It was frequently pointed out that there is a very serious lack of knowledge about how much and what kind of research is now being performed by the utilities, and that a carefully conducted survey of present research activities would be very beneficial in evaluating the situation as it exists today. Many investigations which are really of a research character are being handled as incidentals of system operation or new construction and, thus, are not identified as part of the over-all research effort.

The members of college faculties with whom these problems have been discussed were in unanimous agreement that additional research and technical effort directed toward the problems of the utility industry would attract the increased interest of engineering students who are now inclined to believe that the power industry offers little opportunity to employees of imaginative and creative minds. Some of the financiers and bankers pointed out that an active and aggressive research program is now considered one of the essential factors in selecting companies for investment, and that the electric utility industry would perhaps more easily attract capital needed for anticipated expansions if it were more active in its research efforts. The record of the utility industry in this regard has, of course, been outstanding.

The authors were struck by two significant impressions: the wide divergence of opinion on research policies expressed by the executives of utility companies, and the inescapable feeling that too many utility engineers, as a result of their necessary concentration on everyday problems, do not have a clear understanding of what scientific research actually is or of what research might be able to do to benefit the industry.

Areas of Research for the Utility Industry

Many of the problems of particular significance to the electric utility industry may be classified under the following areas of research:

1. Long-range planning for system development.
2. Application engineering research.
3. Research in operation of utility systems
4. Apparatus development.
5. Research for the future.

Various methods for conducting research in these areas will be discussed in the following to suggest some that appear to be appropriate.

LONG-RANGE PLANNING FOR SYSTEM DEVELOPMENT

The utility industry in the past has been noted for long-range planning in providing for its continued growth. Present methods have been satisfactory, but tremendous postwar growth and rapid industrial changes indicate that new techniques of planning for the future are needed and that simple extrapolations of load curves do not give a true picture of power requirements for more than a few years ahead.

Forecasts of load growth show a disturbing diversity of opinion. Fig. 1 shows the range of estimates of peak load to 1975 as an extension of the load curve since 1945. Some estimates are based on the growth of the recent past with a doubling of load about every 10 years, or less, which will give a peak load of over 400,000,000 kw in 1975. Other estimates apply correction factors to those estimates and arrive at forecasts nearer 225,000,000 kw.

More penetrating studies must be made to analyze the factors affecting demand upon the utility industry. These will include detailed consideration of expected population growth and migration, of the agricultural, industrial, residential, and transportation needs of an area, and considerations of how the energy needs may best be met. Careful consideration of these and other basic elements will provide a much sounder basis for making long-range plans for system growth, not only for the design and building of a particular power station but also for planning 10, 15, or more years ahead.

Paper 55-144, recommended by the AIEE Research Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing December 15, 1954.

J. E. HOBSON and M. S. OLDACRE are with the Stanford Research Institute, Stanford, Calif., and W. A. LEWIS is with the Illinois Institute of Technology, Chicago, Ill.

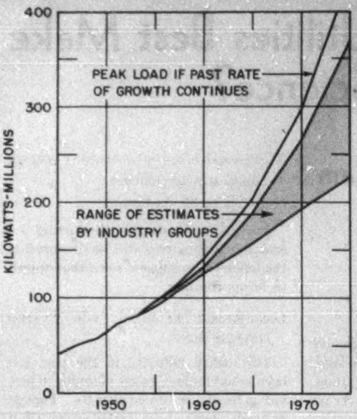

Fig. 1 (left). Prediction of peak load of the electric power industry in the United States, 1945 to 1975

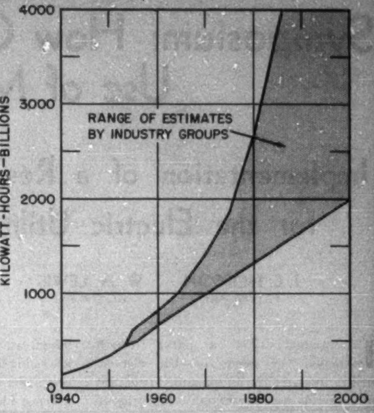

Fig. 2 (right). Prediction of output of the electric power industry in the United States, 1940 to 2000

Of equal or greater interest is the probable total energy output of the electric systems and the production in kilowatt-hours per capita. These are shown in Figs. 2 and 3. Even the most pessimistic estimates for 1975 show more than twice the present figures. This increased per-capita use should satisfy the dreams of the commercial departments but the engineering departments will need to plan far ahead to solve the problems of greatly increased generation, transmission, and distribution.

Of great importance in the future will be the changing fuel-supply picture, not only of individual utilities but for the country as a whole. Revisions currently being made by different authorities in the estimates of fuel resources make it difficult to predict how long they will be adequate for all needs at anywhere near present-day costs. One of the most penetrating of recent studies on this subject was reported by C. C. Furnas.[3] His analysis of the information presented by Palmer Putnam showed that, given expected population growth and increased energy use, the United States and the world face a shortage of conventional energy sources that will become acute in 20 to 50 years. This eventuality will have serious effects on factors of great importance to the electric utilities and must be carefully considered in present planning.

The total demand for energy in this country does not increase as fast as the demand for electric power, but is expected to about double by 1975 and quadruple by 2000 A.D. An indication of what may be expected in total energy demands and population growth is shown in Fig. 4, while the amount of energy available from various sources at costs comparable to present-day costs is shown in Fig. 5. It may be anticipated that new or more expensive energy sources will be needed in the next few decades.

The peak rate of petroleum and natural gas production in the United States will probably occur in about 10 years. When new discoveries are no longer able to keep ahead of new demands, the available supplies will have to be conserved and limited to the more exacting needs to

K—Total solar energy falling on the earth's surface

which their application is particularly suited such as liquid fuel for automobiles and airplanes, and gas for residential heating. The remaining needs will have to be satisfied by using lower grades of petroleum residues and by the increased and more efficient use of coal, lignite, and other solid fossil fuels, or by nuclear and solar energy. A possible means to release oil for power station fuel is the development of batteries or other storage devices for economically using electric energy in operation of vehicles.

The weakest part of the present position is a lack of fundamental knowledge of combustion processes, and that weakness can be overcome only by research of a basic or fundamental nature. Detailed research and economic studies of load demand and fuel use in a given area are local problems peculiar to the company or companies in the area, but the basic problems of fuel availability and fuel processing are of such magnitude and over-all importance that they could be undertaken by the energy-using industries as a whole, possibly through an industry association or other organizations which have such research as one of its major objectives. Support for industry-wide work of this type may properly come not only from the utilities but also from the suppliers of fuel and the manufacturers of equipment.

Application Engineering Research

Equipment supplied by the manufacturers makes use of the best information available to the manufacturers concerning the requirements of operation. It is well known, however, that after machinery is put into service difficulties usually develop that were not anticipated. Improved methods of determining and evaluating important characteristics are required. Investigations to improve knowledge of operating conditions and effects of environment can minimize these difficulties, reduce maintenance expense, and improve the design of subsequent equipment. Such studies are especially important when the equipment is so large or complex that it must be assembled at its final location without trial operation under controlled factory conditions. Investigations of this type may properly be called application engineering research, which has been conducted in an excellent manner by many utilities. It consists of surveys, collection of information and data, laboratory and field work, operation of apparatus under actual plant conditions, careful analysis of results, and co-ordination with similar work by other utilities and by the manufacturers, followed by distribution of results for the benefit of all. Some problems of this type will require more detailed and extensive study than many utilities are prepared to give, but they could be undertaken by technical committees of the industry, either alone or with the aid of colleges or research organizations.

In some cases, the research may require the services of scientists or engineers in special fields not normally employed by utility companies. It may be necessary to obtain information or to develop materials not now available. Thus, special laboratories and staffs may be needed. A few examples of areas where improvements are essential include new materials for very high and very low temperatures; materials for use in nuclear power applications and insulating materials suitable for the extra-high-voltage systems which will undoubtedly be needed in the future.

Discussion with utility executives and engineers has shown that much more work of this character has been done by certain leading utilities than is generally appreciated. It is also recognized that the manufacturers are making significant contributions in this area and will continue to do so. However, it is the authors' feeling that more active participation by the utilities would produce important apparatus improvements that could result in over-all economy for the industry.

Research in Operation of Utility Systems

Much has been done in investigations regarding the stability and control of interconnected systems: the proper protection of systems against disturbances such as lightning, and the protection of system operation against the effects of sudden loss of generation. However, there is a growing awareness that, with the continued growth and expansion of utility systems, research on the problems of system operation is necessary and that many of these problems pose a real challenge for further improvement.

Not only are the ordinary operating problems of interconnected systems becoming more intricate but the requirements for operating the entire system at maximum economy become so complex that conventional methods of calculation are becoming inadequate in many cases. New computing techniques are required for the quick and accurate determination of operating conditions for minimum system losses and for the allocation of those losses to particular generating stations. There is, as yet, no clear understanding of the principles which will permit the ready determination of the most economic use of water power in systems which have substantial amounts of both hydroelectric and fuel power supply. Because of the increasing complications of power systems, the trend toward automatic operation of the systems for maximum economy is clearly evident.

Only a few utilities conduct research on the effects of weather on the operation of the utility system; this subject could be the basis of discussion to show how meteorological research could pay big dividends in guiding operation and loading of the utility system and in preparing for emergencies. The Weather Bureau performs a good service in providing the basic information, but the the utility should be better prepared to apply that information to its own particular conditions.

Another problem seems to be the lack of a clear-cut basis for determining the proper financial arrangements for power interchange between interconnected systems. In the administrative side of the utility business, the best utilization of business and computing machines in the handling of customer billing, inventory control, and other data processing has not been fully realized and further research is justified. It seems evident that a much better understanding of the economics of replacing obsolescent equipment is desirable. In the establishment of rates, there is not yet an adequate and accepted basis for allocating the cost of service to various kinds of load, thereby fully justifying rate differences for separate classes of customers.

It would seem that better answers to these and similar problems would result in enormous savings because of the large volume of the utility business and would, therefore, justify extensive research effort by both utilities and manufacturers. Manufacturers of large apparatus have contributed importantly to the solution of system problems when the results affected the characteristics of apparatus or machines. Similarly, manufacturers of computing and business machines may be expected to participate extensively in research leading to the development of the most effective types of such machines for utility use. Because of the complications of mathematical and computing problems involved in many of these studies, it would seem that research organizations and colleges, which have groups of specialized personnel, could be used appropriately, effectively, and with mutual advantage.

APPARATUS DEVELOPMENT

Many utility executives have stoutly maintained that utility companies should have no part of apparatus development, but should use what has been offered by the manufacturers at a price which includes the cost of research and development. It is the belief of the authors that the primary responsibility of the utilities in apparatus development is to make sure that the job is properly done for the best interest of the utilities. Experience in other industries has frequently shown that research programs are less effective if all interested parties do not participate actively in the planning of the work, the analysis, and evaluation of the results. There is no reason to believe that the same is not true in the electric utility industry. Many examples can be given where utility participation in the planning and testing of apparatus in the development stage has been extremely beneficial.

When the manufacturers are not ready to undertake or carry forward desirable developments, the utilities may very properly initiate and conduct such projects alone, at least until they secure the co-operation of the manufacturers. In short, apparatus development must be a co-operative endeavor in which the users have an important function that is not always fully appreciated.

RESEARCH FOR THE FUTURE

The kinds of research and development discussed in the foregoing are of direct and immediate interest to electric utility companies, but in several instances it has been pointed out that all the essential information is not available and progress will be impeded if new and more penetrating information and data are not developed in both technical and economic fields.

There are several areas of knowledge on which the industry rests where the underlying scientific phenomena are unknown and where further investigation may point to a broader understanding of the physical phenomena and lead to new and entirely unexpected developments. Experience of other industries indicates that effective research on such problems may open up entirely new possibilities which will have tremendous advantages to the industry. Although the need is not so apparent, the returns may be greater than for research that is directed within narrower limits.

The important feature that these areas of research (for essential information or for underlying phenomena) have in common is the necessity for a careful scientific approach in which the abilities and skills of scientists in several fields such as chemists, physicists, metallurgists, and mathematicians as well as economists and perhaps even biologists and psychologists may be needed to make the work effective.

Several research areas for essential information in which the results may be immediately applied have already been suggested. Other basic problems of equal importance to the industry could be named. Areas of research where the industry is in need of broader fundamental knowledge have been mentioned in previous papers.[1,2] These included a comprehensive study of insulating materials in an effort to understand their behavior better and to prepare the way for the development of new and more effective insulating materials; a more precise understanding of the factors affecting corona; a better understanding of magnetism, leading to possible improvements in magnetic materials; a scientific understanding of switching, the electric arc and electrical discharges, in gases, liquids and solids; studies of other methods of converting energy into electricity; investigation of possible new methods for electric energy storage, conversion, and transmission; new knowledge regarding the properties of steam at supercritical pressures and temperatures; and the possibilities for further improvements in combustion of fuels.

It is true that a few electric utilities are already quite active in some research fields either by their own engineering, technical, or laboratory staffs or by sponsoring work at universities or research organizations. Particular mention may be made of the study groups engaged in the development and investigation of nuclear power possibilities. Others have already undertaken the installation of steam generators and turbines operating in the supercritical range. In most cases, these have been spectacular projects and have great publicity value because of their promise of large returns. It is the belief of the authors that many of the less spectacular projects are of broad significance to the industry as a whole, and have great potentialities for improvement but are now receiving inadequate attention under present conditions.

If substantial improvement is to be made in the conduct of desirable research, a suitable mechanism must be established. In the foregoing, several different methods for conducting research were discussed, and some are in actual use. The manufacturers of apparatus as well as others outside of the power industry have conducted much of the basic research but the amount of such research that can be financed on the prospect of early return in apparatus improvements or can be justified from the standpoint of public relations is definitely limited, and the authors believe that the existing methods of financing are insufficient.

Most of the electric industry research projects have been of definitely limited duration with the expectation that they will be terminated as soon as specified goals have been reached. From a long-range point of view the benefits of continuity of effort and thinking are lost although their value has been demonstrated in other industries, e.g., the chemical industry, many times over.

The importance of a cohesive group of

scientists and engineers, covering several areas of training and experience, assigned full time to the study of the industry-wide research problems becomes evident. It should be the function of such a group not only to evaluate continuously the research program of the utilities but also to examine and make recommendations for the research conducted by manufacturers, colleges, and research organizations, whether sponsored or not, and to observe contributions from foreign countries. Its members should be ever seeking new ideas and the adaptation of old ideas to new situations. Such a group would form the liaison between the application engineers of the industry and the fundamental scientists who would be most effective in carrying on the more fundamental work. This co-ordinating group could be in a position to participate in the placing of contracts for sponsored research, either directly on behalf of an industry association, or in the guidance of individual utilities in the sponsorship of work in which the company was particularly interested. The essential belief of the authors is that the implementation of basic research through temporary committees of engineers who have primary interests in other directions will not produce the most effective results.

It has been tacitly assumed in the foregoing that any such co-ordinating research group would have to serve the entire industry and would most surely have to be supported by some form of industry association, either of the utilities alone, or of the utilities and manufacturers together. Experience in other industries and in the conduct of war research has shown that research scientists, particularly in experimental fields, are most productive if they have suitable laboratory facilities at their disposal to try out new ideas in early stages and to check questionable parts of the work done by others, even if all of the work is not done under their direct supervision.

Reasoning along these lines led to the suggestion of an industry-supported laboratory in which the basic and fundamental research activities could be conducted. A research budget in the order of 1/10 per cent of the gross income of the electric utility industry was suggested as being appropriate after an early developmental period.

General Comments and Summary

Several different phases of the research program appropriate for the electric utility industry have been discussed and several methods for accomplishing the necessary research have been outlined. It is believed that no single method or form of organization, to the exclusion of others, would be fully effective or most satisfactory for the conduct of the various classes of research. The needs are many, and the type of problems suggest the possible method of approach that may be most appropriate in each case. The research subjects suggested as examples have been more or less arbitrarily assigned to the different phases of the program but they might have served equally well as examples of some other class of activity. However, consideration of all the different research activities needed seems to show that co-operative action among the utility companies with the manufacturers of equipment, the suppliers of fuel, and in special cases even with other groups is essential if a full measure of success is to be reached.

The long-term objective of any research program is to make possible improvements in the delivery of electric energy at lower cost, recognizing fully that the electric utility industry deserves to prosper only if it can deliver energy more economically in a form which can be more conveniently utilized than competitive forms of energy delivery. Therefore, economic and scientific researchers must bear in mind economic considerations in the evaluation of improvement and in the consideration of alternatives. When research is conducted through short-term projects with a specific end in view, it becomes exceedingly difficult to give proper consideration to all the background economic factors. To give effective consideration to these aspects, it is essential that there be continuity of planning, guidance, and supervision of the over-all research program.

The reaction of college faculties to the ideas and suggestions for a broader and more extensive research and development program have been expressed in the foregoing. The authors have previously indicated their belief that expanded research would have a salutary effect on college graduates and further their interest in the utility industry. Under present competitive conditions it is not sufficient to explain to college faculties and students that the utilities have challenging problems, but this situation must be illustrated by action and results if the better men are to be attracted into the industry in adequate numbers to meet the growing personnel needs. The establishment and sponsorship of appropriate research projects in college laboratories, and the active participation of utility engineers and co-ordinating scientific groups in the planning and conduct of these research projects can well be the means of restoring or creating interest in the power field to the college staffs and students. Otherwise, the gradual drift in emphasis in electrical engineering education will continue toward the electronic and communication fields, to the point where any special emphasis on the needs of the power industry will be as unheard of as specialization in electronics and radio was 30 years ago.

In comparing the electric utility industry with other industries, it appears remarkable that the industry has been able to avoid the establishment of some form of central research organization when so many other industries, with less reliance on technical background, have such organizations in existence. In a recent report[4] it has been pointed out that nearly 50 trade associations have well-staffed laboratories, for the conduct of technical research and that roughly 300 associations have invested their funds in scholarships at engineering colleges; fellowships, etc., at research institutes or the National Bureau of Standards; co-operative research in university laboratories; or privately owned commercial testing laboratories for various forms of research activities.

Although the electric utilities as regulated monopolies subject to government control do not have the same competitive urge as manufacturers, the need for continued improvement in their service to the public is just as great, and methods which have been found extremely effective in other industries should not be passed over by the electric industry without convincing proof that direct research activity would not more than justify its costs. Any doubts that the electric utilities are in a competitive field in their primary function as suppliers of energy are dispelled when attention is called to the importance given to any means that will result in lower investment cost per kilowatt capacity of equipment, or will reduce the cost of operation and maintenance. The competition between electric utility energy delivery and other forms of energy delivery and the competition between various areas of the country for industrial growth and the location of new plants make clear that the industry is subject to all of the forces of competition, and every means which will result in better service at lower over-all cost must be utilized for best results. Any private utility that does not heed this premise becomes a vulnerable target for public power, whether municipal, utility district, or federal.

The experience of many industries has

proved conclusively that long-term research carefully and intelligently conducted will frequently pay tremendous dividends. However, important projects can only be brought to fruition if carried on uninterruptedly, with continuous re-evaluation and study, and with unflagging faith in the ultimate result. Short-term projects, with limited goals, have their value, but the biggest returns can be expected from the more penetrating studies of the bigger and more lasting problems. Visionary dreams still have their place in industrial development and, if carefully nurtured, may produce new trends and revolutionary developments in human progress. The authors cannot accept the belief that the electric utility industry is so mature that it has no need for new methods, but only for improvements on existing methods. With the depletion of existing fuel resources becoming dangerously imminent, with nuclear power upon the threshhold, and with the challenge of solar energy as the ultimate means of meeting man's need for energy when other sources are either exhausted or uneconomical, the pioneering spirit which is shown by some of the utilities must spread throughout the industry. The tool of the industrial pioneer today is scientific and economic research, and the electric utility industry must find the means to utilize its full share of research potentialities to insure its continued growth and success.

Discussion

C. Doble (Doble Engineering Company, Belmont, Mass.): The authors have made an excellent presentation of their plan for a research program for the electric utility industry. Electric power has become one of the most important single basic elements in our modern civilization. Why? Because the biggest factory or chemical plant or even the colossal atomic energy developments all are helpless without an adequate power supply. The main questions are how the utilities can produce and deliver electric power by implementing modern science into their operating requirements and how our modern civilization can make sure that an adequate and reliable supply of electric power is available.

One of the most important problems is to find and educate men who are qualified to do the job and interested to undertake it. The utilities have many important unsolved operating problems that require directed research. Experience shows that much of this directed research should be supported and directed by the utilities themselves because their actual operating experience dictates many of the requirements for new advanced design of apparatus. The equipment manufacturer cannot do the most effective design and develop the necessary new apparatus without data from this basic operating experience. Whenever the research requirements can best be met by outside research organizations, such work should be allotted by the utilities' own organization established for that purpose.

The manpower must come from colleges and it is the colleges' prime function to educate men—not to do commercial research per se. To do this job well some of the college professors must be capable of doing some of the required research. Actual contact with such research keeps them informed and alert to future trends. The type and amount of research allocated to the colleges by the power utilities should be primarily for this purpose and not competitive with commercial research. Direct financial assistance to colleges by the utilities might be done most effectively by establishing scholarships covering work which gives the students an opportunity to realize the scope and magnitude of the utilities' problem in electronics and chemistry as well as heavy currents, which is commonly thought of as the only part of utility work.

C. W. Watchorn (Pennsylvania Water & Power Company, Baltimore, Md.): It is gratifying that the authors recognize the need for more research on economical coordination of hydro and steam generation. There is a widespread feeling that either the problem is too complicated for more than rule-of-thumb procedures, or that further work is impractical. The fact is that the surface of the problem has hardly been more than scratched, and that much work still remains to be accomplished.

Theodore Baumeister (Columbia University, New York, N.Y.): It would certainly seem rational to believe that no one connected with the power industry today would challenge the value of research—even for an established art like that of electric energy generation. Change and progress are inexorable in our technological economy. There is no need today to demonstrate that research leads to an expanding industrial society. Improvements must be consciously sought and persued. For this it is necessary to have many men at work equipped with working tools. These tools cost money. Money is the practical root of the problem in the developmental efforts of the electric power industry.

The tendency up to now has been to leave the costs of research to the manufacturers, suppliers, and vendors of equipment and materials. The research effort by manufacturers has been vigorously supported, with the result that electric service is today more reliable, more plentiful, and more favorable in price to the consumer than any other service which comes to mind. The remarkable part is that the progress has been obtained without an industry-wide research program.

Some of the examples of needed research, on an industry-wide basis, are cited by the authors. Their solutions as to method may be open to debate on various grounds. However, it is essential for the industry as a whole to consider this problem in all its detail to find ways and means of supporting needed programs for progress.

Under the usual regulatory practices of the commissions it is often difficult to demonstrate the validity of the costs of research by a power company itself. If some regulatory bodies are inclined to exclude the costs of advertising household appliances as load builders, there is much uphill work still ahead for those who are research-minded. If it can be reasoned that increased power sales are of more benefit to the stockholder than to the rate payer and costs therefore are chargeable to the former, what are the prospects for finding research funds? Research by its very nature is generally doomed to negative results or to failure. If that were not the case, the answers to problems would be self-evident and no skill would be needed to find those answers. Anybody could do it. Consequently, there is a very real question posed to regulatory bodies, to utility managements and to consumers—how will the charges be allocated in any extensive research program? If the result of the research is negative and the activity must be abandoned, who is going to pay the bill?

At present it would seem that the preferred practice would be to put this burden on the owners of the business. It is doubtful, for instance, that a commission would be willing to burden future rate payers with the cost of a defunct research effort. It is much simpler to pay for research in the investment for equipment which is bought from manufacturers, who in turn have engaged in research. This might be construed as shifting the cost, with the consumer ultimately paying the bill when new equipment is bought. Why not allow research expenditures to be made directly, and consequently avoid the burden of unnecessary duplication of effort among manufacturers? There may be some merit to such argument but there is also the equally valid argument favoring research by manufacturers. While the cost of the research must ultimately be reflected in the selling price of the equipment, there is, at least in theory, the offsetting influence of competitive apparatus and prices of other manufacturers.

The solution to the industry research program which favors sponsorship by equipment manufacturers has merit when applied to specific apparatus. However, there are many types of research problems which cannot be properly or effectively handled by this method. The authors cite such problems and propose some solutions. I believe that the necessary step which must be taken is to find reasonable and acceptable ways in which funds can be set aside for carrying out the recognized research problems.

Howard P. Seelye (The Detroit Edison Company, Detroit, Mich.): The authors have made an excellent analysis of the opportunities for research which are open to the electric power industry. There is no question that there are many fields in which investigation will not only be worth while but will be essential if the industry is to maintain its position as a progressive force. In looking over the rapid progress which has been made during the past 50 years in stimulating the use of electric power and in adequately meeting the demands so produced, it cannot fairly be said that the industry as a whole has been laggard in its research. Much of it has been done by the manufacturers of course, much by the operating utilities, and much by co-operative effort. There is also a great deal of research work under way today as is witnessed by the progress being made or planned into new areas of temperatures, pressures, high voltage, atomic power, and others. No one can say just how much the utilities should have done or should be doing. The measure is the need for discoveries and how well that need is being filled rather than what per cent of income may be spent.

It is believed that the utilities could justifiably increase their activity in the research field, particularly in the direction of correlation and co-ordination of what is now being done, stimulation of more attention to those items which are of particular concern to the operating companies rather than to the manufacturers, and publicity for the efforts and results. The organization and plans of the Edison Electric Institute are directed toward just such a program. It is believed that this could eventually meet the essential needs of the situation which the authors are pointing out. It would seem much too early, however, to consider the development of another independent industry laboratory or of much of the very long-range undirected type of investigation. There are many laboratories and organizations now in existence ready and willing to undertake such work. Perhaps the industry laboratory might some time be found necessary, but for the present much valuable progress could be made by proper correlation, direction, and support of programs using the existing facilities.

J. Stuart Johnson (Purdue University, Lafayette, Ind.): There are many phases of this topic which might be discussed at this time. However, I would like to emphasize just one point concerning the stimulation of student interest in the power field. It is, in my estimation, almost a certainty that unless some means is devised to attract graduating student engineers to the utility industry, it will soon be apparent that only the men who could not locate jobs elsewhere will enter this industry. Granted, there will probably always be a few good men who are interested and enthusiastic about the power industry, but these are not nearly enough to man all utility companies. Many companies have not yet felt this shortage of quality workers, or if they have, they may have attributed it to the national engineer shortage. I am convinced, as one who has observed at firsthand the swing in student interest, that this is not the cause.

Any debate concerning the relative responsibility of the utility and the manufacturer in matters of research and development becomes entirely academic in the light of the fact that the manufacturer is not going to have power men for design either. It may be said it is his responsibility to create the interest. But who gets hurt if improved equipment is not forthcoming? He can probably turn his manufacturing efforts into other directions quite profitably.

The power industry is one of the most vital parts of our industrial America. I am deeply concerned over the possibility of its being unable to perform adequately its functions in years to come, lacking the best personnel available, and the most highly developed equipment possible. The proposal made by the authors for the establishment of a research program as individual and/or group effort represents a very real method of bringing about student stimulation as a natural by-product of its unquestioned economic contribution. I submit, however, that it will be a most profitable by-product.

G. B. Tebo (Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada): The authors quite properly emphasize the need of the electrical industry for more scientific knowledge to be gained chiefly through additional manufacturers' research, and through utility-sponsored research. But possibly too little emphasis has been placed on the changes which should take place in both the attitudes and facilities of some individual utilities if the benefits of this new information are to be fully realized.

Failure to attract engineering graduates into utility work will not be corrected by simply having the utilities encourage more research in the manufacturers' laboratories. Even a central utility-sponsored laboratory or a particular commercial laboratory will seem very remote to the graduate entering a distant utility. Nor will the flow of research information from these laboratories be of much value to a utility which lacks interest in the application of advanced scientific methods to its own immediate problems.

Some utilities have recognized that unique fields for profitable research exist within their own organizations. The logical action for such a utility was to hire a few people trained in research methods and have them assess the immediate problems by planning a research program to deal with them. This sometimes led to procurement of laboratory facilities, and the nucleus of a research establishment was created. Its size depended on the size of the utility served, and on its ability to produce results of value to that utility.

On the surface, the idea of individual company laboratories may look like unnecessary duplication. Actually, the experience of companies operating such facilities indicates that the work consists largely of day-to-day problems particular to that utility and that any findings of industry-wide interest are readily exchanged through the efficient industry associations and little tendency exists to duplicate the research work of apparatus manufacturers.

Many examples could be cited of lucrative research projects which can best be performed in the utility's own laboratory, such as:

1. An improved method of predicting daily peak load for a 3,000,000-kw system improved the accuracy of prediction by 1 per cent. This was accomplished by establishing certain local illumination-load relationships and applying advanced statistical and machine computation methods to available data. One year's saving in cost of spinning reserve repays the cost of the investigation many times over.
2. A study of wood preservation sustained for the past 25 years in the laboratory, in test plots, and in actual service has brought this science to a high state of effectiveness. The prolonged life of more than 1,000,000 poles in service pays handsome dividends to this company. Although the basic results of this pioneering effort have been of value to the whole industry, only in the utility's own laboratory could the local conditions of weather, soil, and pole species be fully recognized.
3. A striking saving in lubrication costs on a 350,000,000-dollar construction project was made by a co-operative effort of the construction, research, and purchasing departments. The lubrication recommendations of the major oil companies were studied, available materials were tested, requirements were simplified, and bulk purchases were negotiated. Over the 5-year life of this project, tangible savings on purchase of lubricants were estimated at more than 500,000 dollars. This was possible only because of the utility laboratory's long experience in the investigation of lubrication problems.

In facing the question raised by the title of this symposium, we should not overlook the opportunities for research within each utility. Nowhere else will be found the same intimate knowledge of the problems, the same sense of urgency in seeking solutions, or the same opportunities to try out and observe the solutions in actual operation. This will not retard, but should actually stimulate, the research activities of the manufacturers, the commercial laboratories, and the universities. Such local laboratories could constitute the chief source of problems for a central utility-sponsored laboratory. They would also provide an essential means of digesting and applying the results of pooled research to the operations of their own companies.

Frank E. Sanford (Commonwealth Associates, Inc., Jackson, Mich.): The authors are in substantial agreement with many others concerning the essential nature of research for the electric utility industry, but they have found a wide divergence of opinions on policies and lack of a clear understanding of the possibilities for increased research.

Perhaps the big questions may be summarized as: how to create a more favorable atmosphere for expansion of research, and how to implement or co-ordinate a program of research if it is to be expanded. These questions are closely related to three more that are basic in any further consideration: Should there be one large laboratory and staff corresponding to those of several other industries? Should more problems be assigned to the universities and to commercial research laboratories, with co-ordination through an industry committee. Or should the present arrangement be continued with major dependence on developments by individual manufacturers?

It is probable that the final answer will be found in a combination of all these possibilities, with the utility industry participating more actively in sponsoring a co-ordinated series of projects for studies in university and commercial laboratories, with projects such as the present nuclear energy developments in individual companies or groups, and with many projects handled in company organizations and co-ordinated as a result of consideration by the various engineering committees.

This combination appears most advantageous for flexibility, for its assurance of breadth in the approach to problems presented, and, very importantly, from the viewpoints of public relations and advancement of engineering education. It is possible that the electric utility industry may ultimately need a single large laboratory, but it appears much more realistic now to use present facilities in a co-ordinated program. Attempting to promote, finance, and staff such a start would be trying to leap before learning to walk.

The real and fundamental need today is to learn more about what is being done, what is considered to be needed, and with that to start building interest, understanding, and confidence. This could be done in a relatively short period of time, but it will not be a simple job and it needs more total time than is usually available to the individual members of a committee.

The first step was made toward such a plan as long ago as 1948, when the Edison Electric Institute Board of Directors approved a research program to start with addition of a research co-ordinator to its staff to aid a research committee. The duties of the committee and co-ordinator were the determination of the extent of research in progress, co-ordination of research, and the making of recommendations for additional research projects which would be considered for approval. It was then expected that the plan would be under way in January 1949.

This action followed recommendations of a committee which had surveyed the situation then and outlined a 5-year initial program. But this first step faltered and, as of today, the 5 years have passed with the discussion once more in exactly the same channel as in 1948 and before.

With time to work out of the postwar situations and the critical requirements and pressures during the smaller war which followed, it is perhaps time to try again. An initial objective should be a survey and compilation of information of activities, possibilities, and needs. Outlining ideas for short-range problems, creating a more active interest and confidence, and establishment of contacts and goals might be the only result of this initial phase. Extension and continuation to include fundamental and basic problems requiring long-range study should follow.

Improvement of present efforts should bring about immediately a higher degree of co-ordination of goals and continuity of existence. The present arrangement of specific projects which are liquidated following each effort would be blended into a program with continuity, correlation, and direction. The paper presented will prove to be very important if it will again stimulate discussion at both engineering and top management levels of the electric power utility industry.

H. H. Brown (Wisconsin Michigan Power Company, Appleton, Wis.): Since we are primarily a utility with most of our power generation coming from hydro plants, we conduct activities in collecting careful hydrological data. Besides the usual collection and analysis of rainfall, runoff, temperature, snowfall, and sunshine hours, we work on other variables. For instance, ground water levels in our drainage area have proved of value in predicting river runoff. We have found that a year with less rainfall but high water tables has produced more runoff than a year with good rainfall and low water tables. Nylon resistivity blocks buried in the ground at different levels have aided in studying the moisture in the soil between the water table and the ground surface. The 4-electrode megger resistivity routine testing has also been valuable in determining water moisture in the soil above the water table. Cyclic studies on rainfall over an extensive area like the Menominee River shed since 1911 have resulted in a major trend curve and the many contributing harmonics. Once a year our company with key personnel devotes an entire day on the review of the last year's activities. These reports are distributed to all parties concerned. We also invite some neighbor utilities to pool all the many ideas and practices. I am sure a pooling of the efforts within our nation and of those from foreign countries as well would be an interesting adventure if due funds could be established. To know the future runoff materially aids in controlling our reservoirs so as to obtain the greatest use factor of pondage without entering a winter with low reservoir levels. I think the authors' suggestion of observing foreign country practices should prove helpful.

Utilities are always fighting competition. Even though we have a monopoly in the territory we serve, we are competing with customer-owned steam turbine generation, for instance, in the paper manufacturing industry. Bottled gas has cut into our electric range and electric hot-water heater expansion programs, particularly in rural and summer resort areas. It therefore behooves us to keep abreast of the times and to give the customer the lowest possible rate consistent with a fair return on our investment.

Since I am located at the heart of the greatest research center of the paper industry, I am cognizant of the importance of research. Possibly through one of the three national utility organizations the authors' suggestions of research in the electric utility industry can become a reality.

J. E. Hobson, W. A. Lewis, and **M. S. Oldacre:** We appreciate greatly the discussers' interest. They all point out the importance of research and development in the electric utility industry, and in general agree that a more extensive research program is desirable and appropriate for the industry, even though there may not be complete agreement on the method by which the research should be accomplished. It is perhaps significant that most of the discussers, in commenting on particular research activity, have paid particular attention to recent developments, or problems that are immediately pressing and relatively little has been said about basic and long-term research for future needs. This tacit omission perhaps lends added weight to our belief that the industry is giving relatively little attention to its basic and long-term needs, and that means must be found not only to find solutions to the immediate problems but to lay a broader foundation for the developments needed for the future.

Mr. Doble stresses the point that it is the prime function of the colleges to educate men and not to do commercial research per se. We would certainly agree with this statement. However, it is generally agreed that the process of education involves not only the imparting of known facts to students but also the development of new knowledge by searching into the unknown. In this respect, we believe that it is one of the important functions of a college to carry on research in fundamental areas where the goal is the development of new information, preferably not for the purpose of meeting an immediate commercial problem but primarily for contributing to the over-all development of the art. In certain individual cases it becomes quite difficult to distinguish between fundamental research and commercial research because of the impossibility of defining specific limits. Nevertheless, the important differences in primary objective will tend to avoid any serious conflict of activity. Commercial research, by its very nature, tends to be specialized around immediate pressing problems, and the techniques developed by established laboratories in their special fields can keep them pre-eminent in their areas so that their continued existence is fully justified. When research is directed toward specific and well-defined goals, and deadlines have to be met, the pressure of research activity can seriously interfere with the educational process, and research in this area hardly belongs in educational institutions.

We agree with Mr. Watchorn that the effective co-ordination of hydro and steam generation is a complex problem, and probably extensive research will be needed for the expected results to be much better than can now be obtained by essentially rule-of-thumb procedures. Nevertheless, we believe that to obtain the maximum economy on systems having both steam and hydro generation research on this problem is justified.

Mr. Baumeister expresses some concern regarding the action that may be taken by regulatory commissions in approving research costs as legitimate charges of public utilities subject to their regulation. We believe that research is, in the final analysis, the most effective means of reducing the cost of service to the customer. Of course, in the beginning, investments in research must be made with the expectation of a future return. However, if that return is not achieved in the long run, research is not justified. In this sense, research expenditures at the present time are in the nature of an insurance policy directed toward lower costs in the future. It is of course not reasonable to look at each research project individually, because some projects will be successful, while others will not be. However, in the long run, a research program must pay for itself in lowered cost, or it should be discontinued. If this principle of research is once established, there seems little question about the justification of modest research charges as operating expenses, in the expectation of future benefits, just as higher installation costs can be justified for more efficient units because later the operating costs will be reduced. We believe that regulatory commissions can be persuaded of the logic and justice of this position. We are confident that, when the utility managements themselves are firmly convinced of the responsibility of utilities for supporting a broader research program, the regulatory bodies can be and should be persuaded to authorize the necessary charges.

Mr. Seelye believes that is is much too early now to consider the development of an independent industry laboratory or much of the very long-range undirected type of investigation. We would certainly agree with him that the need for a laboratory supported by the industry should be developed gradually, and that it would not be prudent to rush into the construction of elaborate laboratory facilities as the first step. However, it is our belief that one of the desirable early steps is the development of a research planning and co-ordinating staff for the industry as a whole that can look toward a more intensive investigation of the longer range and more basic problems of the industry which do not now appear to be receiving adequate attention. As the work of such a group becomes more effective the need for laboratory facilities in certain directions will undoubtedly become acute, and at that stage it will be time enough to initiate laboratory facilities. We do not contend that any great amount of research should be undirected. There is a place for exploratory research into new areas with no preconceived objectives, dictated primarily by the interest and curiosity of the investigator. Research of this type can be most effectively done in college laboratories where research for basic new knowledge is a principal objective. However, when early discoveries indicate interesting phenomena that give some promise of practical application, it becomes possible to develop a co-ordinated and carefully planned program of research to explore the possibilities. It is primarily in the latter area that an industry research organization and laboratory will eventually prove indispensable.

Prof. Johnson has emphasized the need for stimulating the interest of students in the power industry and it is most helpful to have his favorable opinion regarding research efforts for this purpose.

Mr. Tebo is particularly concerned about the relation of the research program to the manpower needs of the industry. We certainly do not contend that an isolated and separate research laboratory, sponsored by the industry, will so change the industry that engineers in great numbers will be attracted to all of the operating companies. However, it is our feeling that, if the industry accepts its full responsibility for an aggressive and forward looking research program at all levels including a central organization for attacking the broader problems and a more aggressive research attitude in the companies regarding their immediate problems, the working conditions within the companies will gradually be changed all along the line, and recruiting problems will become far less difficult. In short, the spirit of research becomes a method of doing business that will permeate not only the research organization but the engineering and business organizations as well, and will tend to bring the industry in step with a modern age that considers research essential to progress.

We agree with Mr. Sanford that there is now a definite need for a further look at the research requirements of the industry, and this review should be thorough, careful, and far-reaching. A desirable starting place is a survey of the research in progress and a broad evaluation of the possibilities and needs. We believe that this evaluation should most certainly include a careful study of the responsibility for the long-term research needs of the industry.

A survey of this type will largely indicate the best methods for accomplishing the desirable research. We agree that the most effective method of accomplishing the desired results will undoubtedly make use of all of the existing research tools, and we feel sure that an industry laboratory will gradually prove an indispensable part of the ultimate program.

Research in the Electric Power Industry

L. R. GATY
FELLOW AIEE

Synopsis: The electric power industry and the research it has done and is doing are reviewed briefly and areas of research which should be pursued more aggressively are discussed. The industry must provide the highest service reliability at the lowest cost consistent with sound practice. Any research that holds promise of fostering this objective should be carefully considered and encouraged either directly or indirectly.

THERE is no question of the need for research. It is the key that has unlocked many secrets of nature for the benefit of mankind. There is every reason to believe that new developments and knowledge will dwarf the progress made up to date. It was research that created the electric power industry and it is proper to examine what part the utility industry should take in an aggressive research program. Certain types of research have been and are being conducted by the utility industry and these will be continued and expanded. There are other types of research that have no place in a prudently managed utility company and these will be avoided. Between these two is a broad band of controversial activity that must be carefully considered.

Many Kinds of Research

Research is defined by Webster as a "careful or critical inquiry or examination in seeking facts or principles; diligent investigation in order to ascertain something." The author has divided research into three groups and defined them as follows: "Fundamental research" is seeking knowledge of the fundamental laws of nature without regard to the usefulness of the knowledge. "Basic research" is taking this knowledge of natural laws and applying it for the benefit of mankind. "Applied research" is seeking ways to improve a product, reduce its cost, or broaden its usefulness.

Research Being Done by Industry

Considered in the light of this definition a substantial amount of research is being carried on by the electric utility industry. Much of this research might have been carried on by industrial concerns or by universities but was initiated by the utilities before other groups became interested. Many of these projects should have been included in the category of research but were not so classed. These include work in the technical and scientific areas and frequently extend well beyond the scope of work usually associated with this industry.

A few of the research projects now

Paper 55-145, recommended by the AIEE Research Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N.Y., January 31–February 4, 1955. Manuscript submitted October 26, 1954; made available for printing December 9, 1954.

L. R. GATY is with the Philadelphia Electric Company, Philadelphia, Pa.

active or completed within the past few years are listed here. This partial list indicates the variety of problems being investigated by research supported either fully or partially by electric power utilities.

1. Research on graphitization of steam piping: An investigation of the phenomenon of graphite migration and means of prevention was sponsored jointly by the Edison Electric Institute (EEI) and the Association of Edison Illuminating Companies (AEIC).

2. Branch circuit overcurrent protection: An investigation of the characteristics and requirements of branch circuit protection was sponsored by EEI and AEIC and was conducted in co-operation with the Underwriters' Laboratory.

3. Pipe-type underground cable research: Factors affecting the rating and operation of high-voltage pipe-type underground cable systems were investigated by EEI and AEIC.

4. Heat pump studies: The joint AEIC/-EEI Heat Pump Committee has sponsored several studies of various phases of the problem including heat storage media. The committee is now carrying on a preliminary investigation of supplemental heat sources including solar heat.

5. Steam contamination: This research was organized to study the factors which govern the introduction of impurities into steam from the water in the boiler and the subsequent deposition of those impurities on the blades of turbines. It was sponsored by EEI, AEIC, boiler manufacturers, and turbine manufacturers and involved fundamental studies in a little-known brand of physical chemistry and the development of new measuring techniques.

In addition, active research has been carried on in the following fields as well as others not enumerated: Electronic accounting machines for billing; artificial resuscitation; load characteristics; furnace performance factors; atmospheric contamination; high-temperature steam generation; welding; and fly ash.

The Cable Engineering Section of AEIC has been very active in exploring many factors which affect cable rating, life, and operation and has received excellent co-operation from the cable manufacturing companies. Preliminary work has been done on investigating the possibility of using extra-high-voltage cable. With presently available insulation, it appears as though cable would have a very low load rating at 345 kv and could carry no load at 380 kv because of high dielectric loss. Research which pointed the way to a substantially lower dielectric loss in the cable insulation would improve the performance of existing cables and permit an extension to voltages in the 300-to 400-kv range.

In addition to these direct projects there have been many carried on by various technical committees of industry organizations. This industry is unique in its policy of free interchange of information among its member companies. Troubles and errors are frankly discussed and all information is made available to other companies having the same problems or equipment. A catastrophe may occur on one system and within a matter of hours it is known and the details are given to other companies. These troubles are discussed and analyzed at committee meetings. In addition, innovations, improved methods, better utilization of equipment and, economic simplification are discussed and the full story is made available to all interested. This atmosphere of frankness and mutual interest has created a committee organization of unusual effectiveness. It permits the entire industry to benefit from the pioneering of each member and allows the group to go forward with accurate scientific knowledge. Without this free interchange the progress to higher voltage, larger units, greater capacities, higher temperatures, and pressures would have been much slower. The industry does not call all this activity research but it is included in the definition given in this paper.

Progress Through Co-operation

There are various needs that must be weighed and evaluated. The utility industry needs a healthy and agressive equipment manufacturing industry. Both of them need alert and forward-looking groups of technical educational institutions, which provide the lifeblood of both industries through the new talent that is trained. A virile and progressive educational program contributes to progress, so ways must be found to keep educational institutions solvent to attract and hold outstanding teaching staffs. One way of doing this is to authorize research projects that will provide financial support and equally important, will stimulate interest in the power industry.

The electric utility industry has just passed its 75th birthday with every indication of a continuing dynamic growth ahead. There is a challenge for the best technical and managerial talent to carry on its traditions and fulfill its obligations. One of the reasons for this success is an extremely close relationship between the utility engineers and the engineers of the equipment manufacturers. Through the years a co-operative partnership has grown up between these two groups that has resulted in unprecedented progress in new and better products with ever increasing efficiency and reliability. The electric utility industry could not have reached its present stature without the developments that have stemmed from this teamwork and the research and standardization that has been made possible. New designs, higher efficiency, greater economy, better reliability, and simplicity of operation have all resulted from this partnership and have permitted cheaper and more reliable electric power to become one of the miracles of industrial expansion. All groups have shared in the benefits of this teamwork and any program of research must not interfere with it.

The equipment manufacturing industry has provided research laboratory facilities and personnel to carry on an aggressive program of research which includes metallurgical, chemical, electrical, thermodynamic, and other fields. This has many advantages to the manufacturer and his customers. It makes available the results to a wide group, it strengthens the sponsor, it provides excellent facilities and technical talent to investigate a problem that may develop suddenly in connection with new products or new applications, and it provides lower costs for the manufacturer that can be passed on to the customer along with a better product. Competition tends to increase the effectiveness of this arrangement and makes it far more productive than a single research center supported by many sponsors. There is nothing that provides a greater incentive than having a competitor get a temporary advantage through improvements in his product.

This research program must not be upset. It is proper that certain types of research should be conducted by the manufacturer and not by the purchaser. The customer should not be expected to do the research to improve the product he is purchasing, although he should make sure the product is the best for the application he has in mind.

The industry today is producing a kilowatt-hour for less than half the fuel required 30 years ago. This has not been brought about by any one group but through the combined efforts of the manufacturers of all types of equipment and the willingness of the utility industry to pioneer by purchasing and operating this equipment. The utility industry has been willing to pay the costs of the necessary research and take the risk of expensive changes. The field modifications made in co-operation with the manufacturer have made many contributions to progress and scientific knowledge. There appears no other feasible way of doing this type of research—a 1,000,000-pound-per-hour boiler cannot be set up in a university laboratory for research purposes, and small scale models do not yield typical results. This activity is not called research but it should be. That is undoubtedly one of the things that could have been more widely publicized in the past.

There are many similar projects which must be undertaken on a full-scale field basis and the research work is done after operation starts. Naturally there are many components that must be designed, analyzed, tested, and modified in the shop before fabrication, but the over-all operation of the device cannot be accurately determined from component information. The necessary field work and many modifications are fed back into the manufacturer's design group and used to improve future products. This type of research makes a substantial contribution to the knowledge of the art and to the welfare and prosperity of the utility business, but does not get included in the discussion of research activities.

Even though a great deal of research and promotional activity is being carried on by the utility industry and by individual electric utility companies there is certainly ample room for improvement and a substantial expansion in the amount of activity. Dynamic and continuing expansion in the industry suggests that an increase in the level of research activity would be appropriate. There are many cogent reasons why the industry should be providing a more progressive research program. One obvious reason is that inherently the utility industry must obtain a long life from its plant investment. Industrial concerns are able to write off equipment on a short-term basis, but this is out of the question for major plant investments of utility companies. Any research activity that will contribute to longer useful life and lower annual cost is highly beneficial.

New Sources of Energy

There is a new source of energy coming to the front—atomic energy. More of the national scientific talent is devoting itself to atomic energy for war and peace than has ever been devoted to a single project. The utility industry is vitally interested in this field and is actively conducting research in many directions. A large number of electric utility companies are participating in one or more study groups investigating atomic energy in all its peacetime power-producing aspects. Chemical, metallurgical, thermodynamic, mechanical, and economic factors are weighed and investigated. This work is being done in the laboratories of universities, industrial concerns, and research foundations. The recent changes in the law will permit greater use for peaceful purposes. The utility industry is now well advanced in its knowledge in this field and fully expects to continue on to the installation of large-scale atomic-energy applications.

The conversion of solar radiation to electric energy has been improved and widely heralded. How does this affect the utility industry? Some of the semi-scientific writers have envisioned a solar converter on every housetop with unlimited power available for all household uses including heating and cooling of the home. It can be said without fear of contradiction that with present knowledge, materials, and costs this is only a dream. But as research adds to knowledge and provides new materials the dreams of the visionaries are often realized or exceeded. Certainly the utility industry must keep abreast of all new developments in this field. There may be other new forms of energy or energy conversion that will appear in the future. When these are discovered through research, the electric utility industry must be ready to use them to supplement the older forms of energy conversion. This may require a research program to apply the knowledge and make the energy commercially useful but the industry should not embark on a program of fundamental research to discover such energy sources.

Progress Through Dissatisfaction

The progress made in the past 50 years can be attributed to dissatisfaction. Customers are eternally dissatisfied with what they have and want something bigger and better. This dissatisfaction extends into the factories and utilities which are always striving for better machine tools, better quality control, and better working conditions. The utilities are dissatisfied with the service they render, with the equipment they buy, with the engineers educated by the universities, with the cost of equipment and the operating expenses, and are always seeking more reliable and economical devices that will be simpler and safer to operate.

This dissatisfaction is healthy provided the desire is for something better and not just for something different. Hobson and Lewis[1] were dissatisfied with the amount of research that was being sponsored in universities by utilities and had justification for it. Their paper was a provocative and able statement of one of the important problems facing the electric power industry. Very little has been done through this channel and much more should be done. But it would be most unfortunate if this did not meet two requirements: first, it must be research which will help the utility industry to move forward; and second, it must be the type of research that can be done properly and effectively by the universities. DuBridge[2] points out the advantages of research, the needs for research, but, above all, the importance of doing the proper kind of research and not merely experimenting for the sake of obtaining financial support. Research in a university can make a substantial contribution to the understanding of natural laws and act as a stimulus to additional research by other groups. The author is dissatisfied with the amount of research the industry is doing, but is also dissatisfied with the reliability of service rendered and with the costs achieved. If such research were to make a substantial improvement in the service reliability or a substantial reduction in its costs, then the problem of the university research groups would be to find facilities and staffs to keep up with the research projects thrust upon them.

Industries hiring technical men have indicated dissatisfaction with both the quantity and quality of the engineers being educated. The electric power industry urgently needs a steady flow of good engineers capable of growth and development. It is essential to stimulate the interest of the teaching staff as well as the students in the opportunities ahead in the power field. One of the easiest and most effective ways of doing this is to provide research projects that will provide financial support for the institution and for the staff and mental stimulation for the staff and students. There are many advantages in such a program, the least of which is that it could be self-supporting and might pay off in substantial direct benefits. In addition, it provides financial support for the improvement of physical facilities, helps to obtain and hold superior teaching staffs that could not be held otherwise, and creates a real interest on the part of the men who are training and advising the students. Consequently, this will result in a more adequate flow of well-educated engineers interested in the power business. Such a plan would also provide a pool of consultants conversant with electric power industry conditions who would be available when unexpected problems arise. There have been many cases where such consultation was desperately needed but was not avilable or was unknown.

Wide Range of Power Industry

The electric utility industry is only a part of the power industry. The field includes the equipment manufacturing industry and all large industries such as mass transportation, automotive manufacturing, mining, and much of the entertainment and communication field. New techniques in the electrometallurgical field require tremendous amounts of power. The aluminum industry has some of the largest hydroelectric developments in the world. Television and radio require large blocks of power and color television will greatly increase this demand. The power requirements of the fabricating and manufacturing industry are increasing steeply with the need for higher product output with lower costs and fewer men. The large factories have extensive power distribution systems built in with the requirement that they must be flexible enough to meet future changes in manufacturing techniques and power requirements.

Co-operative teamwork between the power industry and the educators will provide handsome benefits to both parties. Research provides a medium through which this can be done. There is a broad mutual interest between the educational institutions, manufacturers, contractors, and utilities. This mutual interest should provide a strong incentive to work out a reasonable solution benefiting all parties.

Future of Industry

A brief review of the forecasted growth in electric power use by many experts presents a challenge of the first magnitude. Even if it is assumed that the growth will slow down and the load will double each 15 years, there will be eight times the load by the year 2000. The efficient supply for customers at that time will require new knowledge in the fields of generation, transmission, distribution, utilization, accounting and record keeping. Some of the problems are common to other industries but some are unique with the public utility industry. The sooner this knowledge is available the more healthy will be the growth.

Research by the electric utility industry is essential and a way must be found to strengthen and expand the research being supported by the industry. A tremendous job lies ahead even if forecasts of future growth are only partially fulfilled and every tool must be utilized to assure that this job is done well. Research wisely conceived and properly channelled will assist in this sound growth and help assure that capable technical personnel is available to the electric utility industry.

Discussion

Walter B. Morton (Pennsylvania Power & Light Company, Allentown, Pa.): Mr. Gaty's paper contains some thought-provoking revelations on the need for research in the electric utility industry and discusses in general terms what the electric utility industry is doing in the field of research.

I believe, however, that it might be interesting to mention a few specific examples of what some of the utilities are doing in research and what is being accomplished. While research of some nature or other has been conducted by utilities for many years, it is only since the war that many utilities have organized special research sections, divisions, or departments where specialized personnel can carry out research activities unhampered by schedules and the pressure of meeting scheduled dates.

Electric utilities have co-operated with EEI and professional societies such as AIEE, The American Society of Mechanical Engineers, and the American Society for Testing Materials in some of their research activities among which are the study of the properties of steam at high pressure and temperature, creep characteristics of metals and alloys subject to high temperatures, and resistance of metal and alloys to high gas temperatures and atmospheres.

One of the outstanding examples of the co-operation of the electric utility industry in pioneering research is the current construction of the world's first commercial size atomic power plant soon to be operated (in co-operation with the Atomic Energy Commission) by a privately owned utility. This is the Duquesne Light Company plant to be powered by a pressurized water reactor. In addition to the active construction of a working atomic power plant by one leading utility, more than 50 other utilities are actively studying the possibilities of proceeding with the construction of plants to utilize atomic power on their system. Among these is the Pennsylvania Power & Light Company.

Specifically, the Pennsylvania Power & Light Company has special research divisions in the mechanical and electrical engineering departments. These groups have conducted long- and short-range research studies to develop better design and construction methods, to make available more reliable and less expensive equipment, to improve installations for effecting economies and obtaining safety to personnel, and equipment, and continuity of service. A major objective of this research is to reduce the capital investment, the cost of operating labor, and the maintenance charges of facilities to serve the public with resulting lower cost of service.

Our company and other contiguous companies in this area pioneered many years ago in the high-voltage interconnection of large capacity utility systems to obtain the most economical use of the facilities installed by the interconnected systems. We also pioneered in the investigation and development of lightning protection for high-voltage transmission lines and our answers to these problems are now used almost universally. Our company began the development of equipment and procedures for the handling and burning of small-sized anthracite produced as a by-product and formerly discarded in culm banks as useless. Now we are the largest user of anthracite in the world, both stoker and pulverized methods of firing being developed and used as a result of our research. We developed a new design of thaw shed using hot water instead of hot air or steam for thawing badly frozen cars of coal to permit rapid unloading.

In the electrical field, co-operating with the manufacturers of equipment, our research has assisted in the development of a medium rated 500,000-kva 69-kv voltage fuse for the industry. This development was supplemented by a fault-current interrupting test at rated voltage on the Pennsylvania Power & Light Company system, which resulted in a fuse costing only 40 per cent of the then existing available heavy-duty fuse. We initiated and pioneered, as a result of considerable research, a new procedure for ice-testing air-break switches. The specifications prepared as a result of this research are now used almost universally by all disconnecting switch manufacturers and have effected improvements in the designs of several manufacturers.

We have done considerable work on the study of loading transformers on a thermal basis rather than name-plate rating, as have several other large utilities. These combined efforts have resulted in a material reduction in cost per kilovolt-ampere of transformer capacity required to serve the load and in many cases the need for additional capacity has been postponed for a long period.

We have conducted research work during the past 2 years in the development and necessary tests for the procurement of adequate 69-kv air-break switches for breaking magnetizing and network load current and, as a direct result of this research, our substation designs have been modified to effect a substantial saving in the cost of switching devices.

Immediately following World War II, after considerable research and study we were able to develop standard designs for substations; on any project we have been able to select an available design from seven standard types to fit any condition required on the system from 4 to 220 kv. This not only substantially reduced the cost of the stations but facilitated installation of rush jobs during the critical years following the end of World War II. These designs are not permanent. They are under continuous study and are modified from time to time as improvements develop as a result of research.

Another project we have in process of research, in conjunction with the equipment manufacturers, is the establishment of an adequate thermal rating for high-voltage fuses which is somewhat indeterminate at the present time. This study has not yet been completed.

I think too little emphasis has been placed on the great value of research organizations within the utilities' own forces and too little publicity has been given to the fine work that many of these groups are doing in the various utilities. The close co-operation between these groups and the manufacturers' engineers in developing improved equipment for safety, for greater reliability and for more economical installations has not been given the publicity it deserves.

As Mr. Gaty points out, most of the progress that has been made in the past 50 years can be attributed to dissatisfaction. I hope that we never become so satisfied and complacent that we will no longer find any need for these research groups that are doing so much, in co-operation with manufacturers' engineers, for the improvement in manufacture and utilization of electric equipment. It is not possible to stand still. We must go forward and continued and more intensified research will drive us forward and at an ever increasingly rapid rate.

Eric A. Walker (Pennsylvania State University, University Park, Pa.): The companion paper by Hobson, Lewis, and Oldacre[1] offers a research program to the power industry, which has as one of its themes the suggestion that a central research laboratory for the industry should be started. Mr. Gaty says that the power industry is doing a great deal of research, both by itself, through certain organizations it supports, and also through the equipment manufacturers. I believe there is one important question which has not been answered. "Do the power utilities need more and better engineers than they now are getting?" and, if the answer is affirmative, then, "Why?"

I would like to suggest that the power companies make a statement on the number of 4-year engineering graduates they need over the next 10 years to make it clear to the educators that a market exists and to allow the educators to design a curriculum to fill that market. It would be very helpful if the power companies could indicate quite clearly the type of work they expect these engineers to do. The more clearly this can be done, the better job the engineering educators can do of filling the order. Lastly, it would be extremely helpful if the power companies would indicate what they think is necessary in a 4-year educational program to make such students acceptable to the power industry. I believe they should link the courses and material they would expect the student to cover with the jobs they would expect him to fill. With these data in hand, I am sure that the educators would be much better fortified to try to steer some of their better students into the public utilities.

REFERENCE

1. IMPLEMENTATION OF A RESEARCH PROGRAM FOR THE ELECTRIC UTILITY INDUSTRY, J. E. Hobson, W. A. Lewis, M. S. Oldacre. *AIEE Transactions*, vol. 74, pt. III, Aug. 1955, pp. 545-53.

L. R. Gaty: The discussers emphasize the importance of better understanding and co-operation between the electric power industry and the engineering educators. A research program by the electric utility industry would be helpful but will not in itself correct the unhealthy situation now existing. Inauguration of an over-all industry research program should not be delayed but cannot be counted on to give more than tangible evidence that the industry is progressive and forward-looking and, therefore, attractive in providing a career for engineers

Manufacturer's Research in Relation to Electrical Utilities

E. E. PARKER
MEMBER AIEE

J. BAIRD
MEMBER AIEE

ENGINEERS have a twofold function. They must find ways to increase the value of present products, and they must develop new products. Similarly, any healthy industry must accomplish these same two functions and certainly the electrical utility industry is no exception. Since research and development are vital to the manufacture of products of increased value and the creation of new products, adequate work of this character is essential to the continued growth of the electrical utility industry. Thus, the question becomes immediately not one of justifying research and development but rather one of determining the appropriate areas for research and development to support the utility industry, of deciding how much should be done, and of finding out who can best do the work.

With respect to the interests of the electrical utilities, appropriate areas for research and development include:

1. Basic scientific knowledge.
2. Power generation.
3. Power transmission and distribution.
4. Power system analysis.
5. Power utilization.

To decide how much work should be done in these areas, the present situation is reviewed briefly. The availability of adequate amounts of electric power at reasonable and constantly diminishing costs has been a major factor contributing to the high standard of living in this country. The electrical utility industry has performed an amazing feat in reducing the average cost of domestic electric energy by 32 per cent[1] in the last 15 years, a period during which the cost of living has risen by 93 per cent.[2] In addition to cost reduction, there has been an increase in value of the electrical utilities product through significant improvements in reliability, voltage control, and frequency control.

Though this is an accomplishment of which to be proud, continued progress demands continued research effort. This work will be done by the utilities, consulting engineers, universities, independent research groups, and the equipment manufacturers. In this paper the electric equipment manufacturers' place in research and development programs of concern to the utility industry will be examined, by describing typical activities in each of the five areas outlined in the foregoing. Since conditions surrounding research and development in the industry are not expected to be appreciably different in the future than at present—if the special situation of atomic energy developments can be considered separately—the pattern of manufacturers, research and development now in progress should be a reliable guide for the future. Since the industry is expected to expand, it can be assumed that the amount of research and development will increase proportionately.

This paper is based on certain funda-

Paper 55-245, recommended by the AIEE Research Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted December 8, 1954; made available for printing March 14, 1955.

E. E. PARKER and J. BAIRD are with the General Electric Company, Schenectady, N. Y.

mental premises. These are as follows:

1. The electric equipment manufacturers are in an excellent position to make substantial contributions in research and development for the utility industry.

2. They have the double motivation of wanting to sell not only the equipment for generating and transmitting power but also the equipment that uses this power.

3. They operate in a competitive climate of the private enterprise system where proof of the worth of research and development work must be demonstrated or the work will be discontinued.

4. A great percentage of all applied research and advance development is applied to physical objects, and the manufacturers of these objects are in an excellent position to understand what work is needed and how best to do it.

5. The electrical manufacturers have reason to be proud of past contributions, although they are aware that these contributions were made possible by encouragement and active co-operation from the electrical utility industry. In many cases the utilities have assumed leadership through specifying equipment with characteristics superior to that in production.

Because of the competitive situation in the manufacture of electric equipment, it can be anticipated that the manufacturers will continue to expand their research and development activities in almost every phase of work applicable to the electrical industry as a whole. This is essential if they are to increase the value of their products and develop new products—a necessity for survival in a competitive economy.

This is not to say that the manufacturers do not welcome research programs sponsored by the utilities. They realize that in view of the ever-expanding horizons of science there is need for much research work which the equipment manufacturers are not in a position to do.

Nor is it the purpose of this paper to say that all areas vital to the growth of the industry are being adequately covered by existing research and development programs. This symposium explores ways in which research of specific interest to the utilities may be accomplished. In this paper the type of work done by the manufacturers in these five areas is discussed, and how much, on the evidence of recent accomplishments, can be expected from the manufacturers in the future.

Herein, research will be considered to mean the quest for new knowledge, new processes, and new materials. It includes basic scientific research with no definite device or application in mind, and applied research in which the feasibility of applying scientific principles for a specific purpose is proved. The term "development" is advanced development engineering including the development of an engineering model of a device.

Basic Scientific Knowledge

Conductors, insulators, and magnetic materials are three basic building blocks for all electric equipment. The nature of their behavior has never been wholly understood. Today in the electrical manufacturing companies' laboratories, there is a large amount of research devoted to obtaining better understanding of the nature of conduction, insulation, and magnetic phenomena.

Probably no utility will ever operate any equipment at 440 degrees Fahrenheit below zero, yet much research work is being done on the phenomena of superconductivity below this temperature. At temperatures near absolute zero, some metals lose all their resistance and refute many commonly held theories of conduction. New knowledge of super-conductivity may give a better understanding of how electricity is conducted at room temperatures and provide new information about the basic structure of matter.

Considerable progress has been made recently in understanding the fundamental nature of insulators and, if history is any guide, this work should eventually provide the basis for the development of better insulating materials. When chemists learn how molecules of various substances affect the characteristics of synthetic dielectrics, they may be able to synthesize improved solid, liquid, and gaseous insulators. A related area of basic electrical research, with broad implications for utilities, pertains to corona phenomena including the effect of corona on insulation. Results now being obtained should provide necessary background for the improvement of many pieces of electric equipment.

Most of the magnetic materials now in use are the result of equipment manufacturers' research and development programs. While these materials are vastly superior to their predecessors, there is still appreciable room for improvement which can only be brought about by continued work in the laboratories of the world. For example, today a much better understanding has been gained of the basic mechanism of ferromagnetism, yet in the manufacture of electrical steels there is incomplete understanding of how magnetic properties are influenced by various factor such as rolling temperature and grain size.

Significant work is being done in the area of the structure of metals. The object is to determine why metals behave as they do, with emphasis on failure under stress. In the study of certain important materials, test samples with small cross sections have, under some conditions, exhibited much higher strength per-unit area than large pieces of the same geometrical pattern. The need for knowledge of this phenomenon increases directly with the demand for larger equipment and higher design stresses. Single-crystal filaments of a large number of different metals and compounds have been grown and submitted to extensive physical tests. In the case of iron, strengths of up to 1,000,000 pounds per square inch have been obtained in single-crystal filaments. While this strength is currently of little engineering value because of the small size of the filaments, it may lead indirectly to the development of new high-strength, high-temperature alloys with vital applications in the utility industry.

Only a few examples of the manufacturers' research programs of direct or indirect benefit to the utilities have been discussed. There is also important research in the development of new light sources, arc phenomena, electron irradiation of materials, semiconduction, and nuclear science—just to name some of the more important.

Power Generation

An area where the contribution of the electrical manufacturers can be readily measured is the development of improved steam-electric generating equipment. A significant portion of the real cost-cutting enjoyed by the consumer of electric power has come about through increased steam-electric generating-plant efficiencies. Fig. 1 shows a plot of the trend of coal consumption per kilowatt-hour for steam-electric generating plants in the United States during the past 50 years. The upper curve shows the average coal consumption rate of all plants while the lower curve shows the coal requirements of the best plant in service in any particular year. These two curves are based on the utilization of coal with the heating value of 12,500 Btu per pound. Continued improvement in steam-electric generating station efficiencies is intimately tied to research in such fields as metallurgy and combustion, and to the development in equipment designs.

In addition to basic research, there is a large amount of work in the fields of material and process development as well as work to extend the knowledge of the engineering sciences, all directed toward improvement of power generation equipment. Examples of this are the search for new materials, for new knowledge of how better to apply available materials, and for improved dynamic, thermodynamic, and mechanical designs. Study of fuel combustion recently has been emphasized in the research and development laboratories of the United States. This may lead to self-pressurized combustion, eliminating induced and forced draft fans as well as reducing boiler sizes. The search continues for new thermal cycles, with increased value to the customer as the goal. Work on the commercial gas turbine falls in this area.

At least a brief comment must be made on the application of atomic energy to the utility industry. This differs from the areas mentioned in the foregoing in that the major research expenditures are being made by the Federal Government, and the magnitude of these expenditures is so very large that atomic research by manufacturing companies would be small in comparison. Governmental restrictions, while necessary, have also limited freedom of effort in this area. Despite this fact, the electrical manufacturing companies are attempting to stay abreast of the field and to create a pool of trained manpower through two approaches: conducting government-sponsored atomic energy research, and expending their own funds to solve specific atomic energy problems.

Transmission and Distribution

Two foundations upon which the modern utility system has been built are: economical and reliable transmission of power over appreciable distances at a reasonable cost, and economical systems for local distribution. The electrical manufacturers have devoted, and will continue to devote, much time and money to research and development in this area. In the past, this work has resulted in improved insulators, new understanding of corona phenomena and arc phenomena, and fundamental knowledge of power transmission and distribution system problems. Typical developments have provided high-speed and high-capacity circuit breakers, lightning-arrester improvement, and transformer designs combining greater reliability with less cost, weight, and volume.

The equipment manufacturers' laboratories for development of transmission and distribution equipment are unparalleled. They include high-voltage generators capable of producing simulated lightning strokes, high-current surge generators for studying the effect of lightning currents on transmission line equipment, short-circuit current generators for studying switchgear performance, high-capacity testing transformers, facilities for transformer noise studies, and equipment for development and testing of new materials.

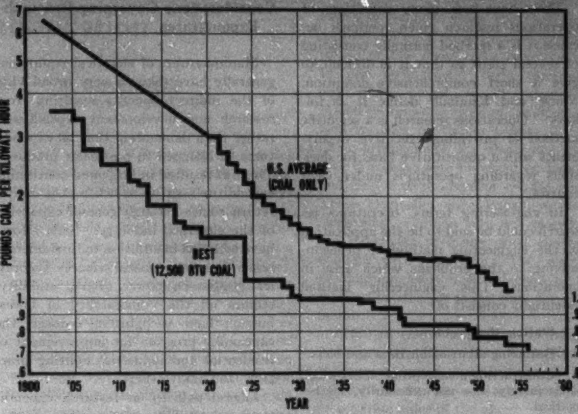

Fig. 1. United States steam-electric generating station coal rate

Much remains to be done in the study of transmission and distribution. Examples are investigations of radio noise suppression and the development and application of improved dielectrics, magnetic materials, and economical designs for higher capacity circuit breakers that will almost certainly be required in future system interconnections. The development of a computer for remote reading and automatic billing of all types of utility meters offers an engineering challenge. However, it appears doubtful that the present general pattern of transmission and distribution will be upset, although possible extension of underground systems making use of improved dielectrics and cable construction must not be overlooked.

System Analysis

System analysis, or system planning as it is frequently termed, is an area where the electrical manufacturers may be of help to the utilities, but where responsibility inherently rests with the utilities. Utility effort in this area, on the part of their own engineering staffs or through the services of consulting engineering firms, is advantageous to manufacturers since such studies normally point the need for the development of improved system equipment.

Even though basic direction for system analysis must come from the utilities, the engineering staffs of the equipment manufacturers are able to make appreciable contributions because of their specialized experience and facilities. For the utility to obtain maximum advantage from such service by the equipment manufacturers, it must maintain a competent staff capable of understanding and contributing to the solution of system analysis problems.

While most utilities individually support system analysis operations, co-operative research and development among groups of utilities has been evident. This is being done to some extent at present for regional planning, in the use of network analyzers, and in the solution of other operating problems of mutual interest such as the economics of high-voltage transmission interconnections.

The complexity of the technical and techno-economic problems, many of which have political overtones, is constantly increasing. There has been a new tool, or perhaps it is more accurate to say concept, developed immediately prior to and during World War II which holds much promise to improve the effectiveness of managers by applying a systematic approach to management problems. Thus the manager may base his decision and action on facts developed through a systematic method rather than on personal experience. It is essentially the application of engineering techniques to the problems of management. This method has become known as operation-research.

There have been many definitions of operations research given, perhaps because it is a method normally consisting of several steps so that it is difficult to give a short comprehensive definition. Morse and Kimball[3] define it as follows: "Operations research is a scientific method of providing executive departments with a quantitative basis for decisions regarding operations under their control."

In engineering terms, operations research could be said to be the application of the engineering method of problem-solving to the problems which arise in operations. This engineering method essentially consists of:

1. Stating the problem.
2. Gathering all available data and facts.
3. Constructing a conceptual model which is frequently, but not necessarily, mathematical.
4. Where pertinent, solving the mathematics and applying of boundary conditions to obtain a relationship of variables.
5. Interpreting results in view of completeness of data and simplifying assumptions.

Many of the methods of operations research already are being used by the utility industry.[4] These methods unlock a great storehouse of human knowledge which may be successfully applied to situations that up to the present time have been considered too chaotic, complex, or uncertain for any but intuitive solutions based on personal experience.[5]

Power Utilization

The very rapid increase in power consumption has been a major factor in the lower cost of electric power. For example, increased demand for power and the interconnection of power systems have permitted the installation of larger generating units with higher efficiency and lower labor and maintenance costs.

Both the wider use of existing devices and the development of new devices which depend upon electricity for power have contributed to the load growth. Devices that are important new load builders include air conditioners, television, household clothes driers, and the heat pump. In the industrial and commercial area, many developments such as new light sources and lighting techniques and new electric equipment for use in electrometallurgical and electrochemical processes contribute to power demands. Many of these devices have been the product of manufacturers' research and development efforts, thus serving the interest of both manufacturer and utility.

Considerations Governing Research Expenditures

Manufacturers of electrical equipment generally have taken a very broad view of the indirect benefits resulting from research and development expenditures rather than demanding that all expenditures be assigned to particular products. This has resulted in large and continuing expenditures in areas where the major return comes through general expansion of the electrical industry. Such efforts have included in addition to fundamental research in the physical sciences, theoretical studies on power system stability, studies on the vulnerability of transmission lines to lightning damage, the continuing program for improvement of residential and industrial lighting practices, and many others.

Liberal policies on research expenditures permit better integration of programs and allow the inclusion of work which could not otherwise be done. For example, work on improved dielectrics is supported by continuing studies on the theory of dielectrics and on corona effects in dielectrics. However, the liberal policies place an increased burden on the judgment of the personnel directing the work.

From the manufacturers' viewpoint there appear to be many areas where research and development expenditures by the utilities would be more fruitful than in direct equipment development programs of the type carried on by the electrical manufacturers. One of the many examples of utility research was the study of steam-boiler water treatment, a program that effectively augmented the work in boiler and turbine design conducted by the manufacturers. In addition to this type of research, closely correlated with manufacturers' efforts, there will continue to be many system problems in connection with the expansion of the country's power requirements. Solution of system problems will be directly dependent on research and development programs conducted by the utilities.

Looking Ahead

Research and development programs may be divided into two general classifications: an evolutionary area, and an area where new concepts alter the basic way in which a particular task is accomplished. This latter could be thought of as a revolutionary area. The evolutionary category might include all improvements in existing classes of equipment even though some of these might involve revolutionary concepts applied to the improvement of an old idea or device such as the magnetic floating of watt-hour meter rotors.

It is much more difficult to estimate or even guess what revolutionary progress will be made in the electrical utility field. There is no difficulty at all in making up a long list of revolutionary ideas; however, it is not easy to evaluate which of these ideas may ultimately lead to a practical commercial development. In the category of things that may be done but which do not look promising for the near future—either because of the state of the art, inherent limitations, or the economic environment—are such items as solar energy converters for the production of commercial blocks of power, electronic refrigeration systems, household atomic power systems, and the use by utilities of fuel cells, i.e., devices for the direct conversion of chemical to electric energy. Undoubtedly the most promising revolutionary development at the present time is the generation of electric power from atomic energy. This is a problem requiring a great deal of research and development, but there seems to be very little doubt about either the ultimate outcome or the economic justification.

Co-operation between equipment manufacturers and the utilities has brought the electrical industry to a position where it can look toward the future with unrivaled optimism. It is fortunate that this co-operation extends to the fundamental levels of research and development. It is safe to predict that the electric equipment manufacturers will continue to allocate millions of dollars per year to research and development in areas of vital interest to the utility companies. This will be done in the competitive climate of the private enterprise system where the need for demonstrating the worth of accomplishments is an effective control to assure maximum results from research expenditures.

Electric Defibrillation

W. B. KOUWENHOVEN
FELLOW AIEE

W. R. MILNOR
NONMEMBER AIEE

APPROXIMATELY 100 electric utility employees die each year as a result of accidental contacts with electric circuits. For years manual artificial respiration has been the only accepted first-aid method for victims rendered unconscious by an electric shock. Analysis of the accident statistics, however, shows that approximately a third of the shock victims who receive artificial respiration with the promptness that should give promise of success, fail to recover. There is good reason to believe that many of these failures are due to the effects of electric currents on the heart.

It has been clearly demonstrated that the heart is susceptible to electric currents. The passage of a small electric current through the heart may destroy its rhythm and throw it into a twitching state called ventricular fibrillation. In this state the circulation of the blood ceases and unless the heart action is promptly restored, death ensues. Ventricular fibrillation not only occurs in the electric-shock field, but also in surgical cases. The only known method of successfully arresting ventricular fibrillation is to send sufficient electric current through the heart to stop the twitching of the muscles. Prevost and Batteli[1] reported in 1899 that they had been successful in arresting fibrillation in the dog's heart by sending either a capacitor discharge or an alternating current through the heart. In their work they opened the chest and place the electrodes directly on the surface of the heart.

The a-c method was studied by Kouwenhoven and Hooker[2] who reported their success with the method and developed apparatus[3] for use in hospitals. With this apparatus a 60-cycle alternating current of 1.5 to 2 amperes, at 120 to 130 volts, is sent through the heart by means of electrodes placed directly on opposite sides of the heart, which must be exposed by surgery. The lives of many patients, whose hearts go into fibrillation during surgery, have been saved. Beck[4] reported in 1947 the first successful defibrillation of the human heart, with the complete recovery of the patient.

In hospitals, the alternating resuscitating current is sent through the exposed heart either in a single application of 1/4 to 1/2 second duration or in a series of five or six short pulses, each approximately 1/10 second in length. The latter method is known as serial defibrillation.

In the field it is not feasible to open the chest and place the electrodes directly on the heart. Therefore, in a field defibrillating method, the electric current must be sent through the heart by electrodes properly placed on the surface (skin) of the chest. In addition, the field method must be one that may be safely applied to a normal beating heart as the presence of fibrillation can only be detected by an electrocardiograph. Among the first to study the defibrillation problem in animals without the opening of the chest were Ferris and Williams.[5] They used sheep as the experimental animals and were successful in defibrillating the sheep's heart by sending approximately 25 amperes at 3,000 volts through the animal by means of electrodes fastened on opposite sides of the chest.

The Research

Because of the importance of this problem in the electric utility field the Edison Electric Institute in 1951 provided funds for a study of the possibility of the development of a method of recovering the fibrillating human heart which would make it unnecessary to open the chest, a method which would be safe to apply in the field as well as in the hospital, and the development of defibrillating equipment which would function in either environment. This study has been carried out at The Johns Hopkins University, and is one in which its schools of engineering and medicine, and its hospital, co-operated.

Experimental Procedure

In this study dogs weighing from 8 to 20 kilograms were used as the experimental animals. All of the animals were anesthetized with morphine and ether. A tube was inserted in the trachea and positive pressure artificial respiration using ether and air was administered. During the periods that the heart was in fibrillation, the ether was cut off, so that the condition would be similar to normal artificial respiration.

When the animal was anesthetized, the hair was removed from the chest with clippers. Two arrangements of the electrodes on the chest have been studied. In one arrangement chest electrodes, each 4 by 6 inches, of soft copper were placed on opposite sides of the chest and held in place by rubber bands. In the other arrangement the electrodes, each 5 by 5 inches, were mounted on handles and held by the operator on the chest. These electrodes were known as hand electrodes. Cardiac jelly was placed on the electrodes to insure good electrical contact with the skin. The electrocardiograph leads were attached to the four extremities for monitoring the heart action.

After an electrocardiogram of normal heart action had been taken, the heart was thrown into ventricular fibrillation by the application of a 120-volt a-c shock applied to opposite sides of the chest. The condition of the heart was checked with the cardiograph. When the heart had been left in fibrillation for the desired length of time, the resuscitating current was sent through the heart by means of electrodes on the surface of the chest. Following this an electrocardiogram was taken to determine the effect on the heart of the defibrillating current.

Results

In this section the characteristics of the heart during fibrillation are treated first. This is followed by reports of successes and failure and the hazard involved in the use of a capacitor discharge, in the use of a series of short a-c pulses (serial defibrillation) and in the use of a single long pulse of alternating current.

Fibrillation Characteristics

If the chest is open and the heart visible, the duration of the fibrillation can be estimated, to some extent, from the appearance of the heart. During the first minute the fibrillation is characterized by a vigorous fine twitching. The heart has a good tone, is of pinkish color, and only slightly or not at all dilated. At the end of the second minute the fibrillation vigor

---

Paper 55-95, recommended by the AIEE Safety Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N.Y., January 31–February 4, 1955. Manuscript submitted October 19, 1954; made available for printing November 18, 1954.

W. B. Kouwenhoven and W. R. Milnor are with The Johns Hopkins University, Baltimore, Md.

The authors wish to acknowledge the generosity of the Edison Electric Institute in providing funds for carrying out this investigation. The valued assistance rendered by L. Ferris, W. R. Smith, and Dr. H. B. Williams is appreciated.

is noticeably diminished, the twitching is less rapid and coarser, and the heart is rather flabby. At the end of the third minute, the twitching is slower, coarser and undulatory. The heart is cyanotic, dark in color, and definitely dilated. If fibrillation is arrested at the end of the third minute, the heart muscles may be so weakened by anoxia that it is incapable on its own of beats powerful enough to circulate the blood. It is doubtful that unless the circulation is restored in 4 minutes, there is much chance of life.

In the operating room with the chest open, the hand may be inserted into the chest cavity and the heart squeezed or massaged so as to produce effective circulation of the blood. It is possible, by means of massage, to restore an enfeebled heart to normal vigor. In fact, the circulation of oxygenated blood has been maintained in a living human being for over an hour by heart massage. Then, when the hospital defibrillating equipment became available, the fibrillation was arrested by alternating current. The patient recovered and was later discharged from the hospital with all of his faculties.

In the field it is not possible to massage the heart, but it is possible to bring the twitching ventricles to rest by the passage of alternating current through the chest even though fibrillation has continued for 3 or more minutes. In such cases it may be possible to drive the heart by the application of small electric impulses[6] to the surface of the chest, and thus aid the weakened organ in re-establishing the circulation of the blood.

Capacitor Discharge

The use of a capacitor discharge for defibrillating the heart is an intriguing one, because of the wide use of portable capacitor discharge apparatus in the flashlight photographic field. There is, however, little information in the literature on the effects of capacitor discharges on the heart.[7] Therefore, a series of experiments was first made on animals with the chest open and the heart exposed. In another series of experiments tests were made with the electrodes on the surface of the intact chest.

OPEN CHEST

A total of 135 experiments were made on the exposed heart in which it was allowed to remain in fibrillation without massage for a period of about 30 seconds. The capacitors ranged in size from 4 to 45 microfarads and the charging voltages from 150 to 1,000 volts. It was found that if the charging voltage was 600 or more volts and the energy stored in the capacitor was at least 5-watt-seconds that the discharge was effective in stopping the fibrillation, and the heart would resume normal beating. These results agree with those of Mackay and Leeds.[8]

Capacitor discharges of 5 to 12 watt-seconds at 600 or more volts were sent through the exposed heart in 57 experiments, in which the heart was allowed to remain in fibrillation, without massage, for a period of 1 to 3 minutes. In these tests there were 32 successful recoveries and 25 failures.

CLOSED CHEST

With the information obtained from the experiments on the exposed heart, experiments were carried out on dogs with the 4 by 6-inch electrodes on opposite sides of the unopened chest. Capacitors of 50, 75, 100, 175, 225, and 1,250 microfarads, charged to voltages of from 4,000 to 450 volts, were discharged through the chests of 35 dogs whose hearts had been in fibrillation from 20 to 60 seconds. There were 13 successful resuscitations and 22 failures. It was found that if the heart had been left in fibrillation for more than 25 seconds the chances of a successful recovery were very slight.

HAZARD CAPACITOR DISCHARGES

In addition, it was found that discharges of this magnitude might result in either cardiac standstill or ventricular fibrillation, when sent through the intact chests of animals whose hearts were beating normally.

CAPACITOR FAILURES

Whenever a capacitor discharge failed to arrest ventricular fibrillation, recourse was had to alternating current. It was found that in many instances, the fibrillation could be arrested by a resuscitating current from the 60-cycle supply lines, even when two or more successive capacitor discharges had failed. Therefore, our attention became focused on the use of alternating current for defibrillation. This does not mean that the capacitor discharge method has been completely abandoned. At intervals, capacitor discharges of various circuit parameters are tried to determine their effectiveness. To date, this phase of the work has not produced any encouraging data.

There are, however, an infinite number of capacitor discharges available and, in addition, there are combinations of capacitors with inductance, that may be effective. It has not been possible to investigate all of these parameters, and there is a possibility that there exists some unique combination that may prove effective. All new suggestions and ideas are being investigated.

Serial Defibrillation

All of the serial defibrillation experiments were made with the electrodes on the closed chest. In the initial tests, alternating currents of 8 to 10 amperes were sent through the chest, in a series of pulses, each of approximately 6 cycles' duration. They were applied by hand, at the rate of one pulse per second. These were effective in arresting the fibrillation, and special electronic equipment was constructed for applying the pulses of a fixed duration at an accurately controlled rate.

HAZARD SERIAL DEFIBRILLATION

The serial defibrillating current was applied to eight dogs whose hearts were beating normally. Results were surprising. In six of these cases, the application of serial defibrillation threw the dogs' hearts into fibrillation. The further study and use of serial defibrillation was therefore abandoned, because the hazard it offered to the normal heart.

A-C Defibrillation

In this method the defibrillating current was sent through the chest of the animal in a single continuous application lasting about 1 second. The current was sent through the chest in either the transverse direction, that is from the right side to the left side, or in the longitudinal, or head-to-foot, direction. Electrodes of soft copper, each 4 by 6 inches in size, were fastened to the sides of the chest by rubber bands for the transverse direction. A pair of 5-inch by 5-inch soft copper electrodes mounted on handles, and known as hand electrodes, as shown in Fig. 1 were used for the longitudinal current path. One hand electrode was placed on the upper end of the breastbone at the neck and the other hand electrode on the stomach pressing upward against the diaphragm.

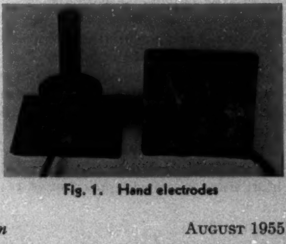

Fig. 1. Hand electrodes

CHEST ELECTRODES

The passage of a 60-cycle current of 8 to 12 amperes at 480 volts was found to be a good method of arresting fibrillation. In all, 107 experiments were made on dogs using this method. The hearts of these dogs were allowed to remain in fibrillation for various lengths of time. Artificial respiration using air was maintained during the period of fibrillation and the anesthesia was not turned on again until the heart had resumed beating and the pulse could be detected. The results of the 107 experiments are given in Table I. This table shows the duration of fibrillation before the resuscitating current was sent through the chest, the number of dogs tested, the number of cases in which fibrillation was stopped, and the number of dogs that recovered completely and were returned to their cages alive. The fibrillation was stopped by the alternating current in 68 per cent of the experiments. If the resuscitating current is sent through the animal within 1¹/₄ minutes after the fibrillating shock, the chance of a successful recovery is a 50-50 one. If it takes 2 minutes to apply the current, the chance of success is very slight.

Table I. Resuscitated Alternating Current, Transverse Direction

Chest Electrodes, Each 4 by 6 Inches, on Opposite Sides of the Chest

Duration of Fibrillation, Seconds	No. of Dogs				Percentage	
	Total	Fibrillation Stopped	Lived	Heart Beat	De-fibrillated	Lived
30	12	10	9	9	83	75
45	11	10	9	9	91	82
60	37	26	16	16	70	43
75	11	6	3	3	55	27
90	11	6	3	3	55	37
105	4	2	1	1	50	25
120	10	5	0	0	50	0
150	8	5	0	0	63	0
180	3	2	1	1	67	33

In cases where the resuscitating current stopped the fibrillation, but effective beats failed to follow, it is believed that the application of small stimulating electric currents to the surface of the chest may aid a weak heart to re-establish the circulation.

A-C HAZARD CHEST ELECTRODES

The hazard involved, in the use of a single continuous pulse of 60-a-c resuscitating current of 8 to 12 amperes was studied by applying it to 43 dogs whose hearts were functioning normally. In no instance was there any injury, and a number of the animals were kept for from one week to two months before being used in subsequent experiments. Autopsies showed no gross evidence of any trauma. The temperature rise in the heart was less than 1 degree Fahrenheit and, under the skin at the center of the electrodes 11 to 12 degrees Fahrenheit.

On the basis of 43 successful experiments, one cannot state that the method is absolutely safe to apply to a man whose heart is beating normally. The chance of its causing accidental death are, however, less than one in 1,000.

HAND ELECTRODES

The hand electrodes were not attached to the animal. The operator, wearing rubber lineman's gloves, held the electrodes, which were smeared with cardiac jelly, on the skin of the animal. One electrode was pressed against the upper end of the breastbone at the neck and the other just below the floating ribs was pressed upward against the diaphragm. Both electrodes were held either on the mid-line or very slightly to the left of it.

To date 58 tests have been made with the hand electrodes. In only four of these did the resuscitating current fail to bring the twitching heart muscles to rest. The resuscitating current values have ranged from 4 to 6.25 amperes at 450 to 500 volts, 60 cycles. If the heart has been in fibrillation for 1 minute, the length of time that the resuscitating current was applied was about 1 second; for 2 minutes of fibrillation, approximately 2 seconds.

The results obtained with the hand electrodes are given in Table II. With these electrodes, the fibrillation was stopped in 93 per cent of the experiments. Eight of these dogs, however, lived for only a few minutes after the heart had started to beat again. Perhaps these could have been saved, had there been equipment available for driving the heart. The same observation applies to other dogs, whose hearts were at standstill following the application of the defibrillating current.

Table II. Resuscitating Alternating Current, Longitudinal Direction

Hand Electrodes, Each 5 by 5 Inches, One on Breastbone at Neck and the Other on Stomach Pressing up Against Diaphragm

Duration of Fibrillation, Seconds	No. of Dogs				Percentage	
	Total	Fibrillation Stopped	Lived	Heart Beat	De-fibrillated	Lived
30	5	5	5	5	100	100
60	14	14	13	14*	100	93
75	6	4	1	1	67	17
90	24	21	7	14†	87	29
101	1	1	1	1	100	100
120	7	7	1	2‡	100	14
180	1	1	0	0	100	0

* One animal's heart beat for about 5 minutes. Its heart however, was too weak to re-establish and maintain the circulation of the blood.
† Seven animals lived for several minutes.
‡ One animal lived for about 5 minutes.

HAZARD HAND ELECTRODES

The resuscitating current has been sent through the bodies of eight normal dogs for periods from 1 to 2 seconds without causing any injury. In addition, a number of dogs, which had been used in several successive experiments, have been autopsied, and no evidence of gross trauma has been found.

Promptness

The question naturally arises: "How soon must the resuscitating current be current be applied if it is to be effective?" The answer is: "The sooner, the better." At 1 minute the chance of success is nine out of ten; at 1¹/₂ minutes one out of three; and at 2 minutes, only one out of seven. These chances may be bettered if the heart can be effectively driven by an artificial pacemaker. Promptness in getting to the shock victim is just as important here, if not more so, than it is in starting artificial respiration.

Time is important to the human brain, which is a delicate mechanism. If it does not receive oxygenated blood for a period of 5 minutes, it may deteriorate to such an extent that should the shock victim be successfully resuscitated, he will live on as a mentally deficient individual. Therefore, promptness in heart resuscitation is essential.

Summary

This paper may be summarized as follows:

1. The capacitor discharge method of stopping fibrillation was found to be unsatisfactory because of its ineffectiveness after the heart has been in fibrillation for more than 30 seconds.

2. The serial defibrillation method using pulses of alternating current was found to be dangerous to normal hearts.

3. The best method found for defibrillating the ventricles was a single application of 60-cycle alternating current lasting approximately 1 second.

4. The most effective direction of flow through the chest of the defibrillating a-c current is the longitudinal, head-to-foot direction.

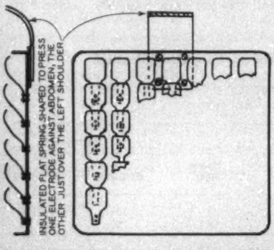
◆

Discussion

G. R. Radley (Cutler-Hammer, Inc., Milwaukee, Wis.): For years I have been anxiously awaiting this report which tells how apparatus can be constructed which has a good chance of saving the life of a victim of accidental electrocution in which the circuit conditions were such that fibrillation of the heart resulted in death in spite of prompt application of even the more efficient back pressure-arm lift method of resuscitation.

At the experimental laboratory where I am employed, there are about 50 engineers. Each year new college graduates arrive who cannot immediately learn how to handle the hazards inherent in working with voltages up to 15 kv. Four persons in the last few years have met their deaths in Milwaukee from only a few seconds' contact (hand to hand) with 440 volts, even though the Schafer method of artificial respiration was begun within 2 minutes.

I propose the design shown in Fig. 2 for use in electrical laboratories. That the very minimum of time be lost in applying electrodes, two 5-inch by 5-inch plates should be attached at the two ends of a spring steel strip shaped like the capital letter J. With this design only the necktie need be removed and the shirt and undershirt unbuttoned or ripped open. With the patient lying on his back the short end of the J is hooked over his left shoulder, the long end lying against the body with the lower 5 by 5 plate contacting the abdomen ject below the lower ribs. He is then rolled over to his face in which position the lower electrode is firmly pressed against the abdomen by his body weight while the upper electrode is pressed against the back of the shoulder close to the neck and held by the spring pressure. In this position, the back pressure-arm lift method can be begun and continued with only a momentary interruption while the countershock is being applied. A hurried test for pulse is made by an assistant pressing a finger against the side of the Adam's apple, reaching in between the arms of the man who is applying the resuscitation. If no pulse can be detected, another countershock must be given. Some cases have required 10 countershocks. One life was saved after 23 shocks. Especially where several shocks are required it is necessary to maintain the resuscitation, for revival cannot be accomplished without oxygenated blood.



INSULATED FLAT SPRING SHAPED TO PRESS ONE ELECTRODE AGAINST ABDOMEN, THE OTHER JUST OVER THE LEFT SHOULDER

Fig. 2. Principle of yielding surface electrode for applying defibrillating current to exterior of human body. Electrodes to be covered with cloth sacks and kept inside boxes partly filled with cardiac jelly so as to be ready for instant use at all times

To obtain as large an area of contact as possible with the far from level shoulder and abdominal surfaces, I propose to cover the 5-inch by 5-inch metal electrode plates with about 50 flat springs whose upper broad ends are cylindrically curved so as to make contact through a range in position of at least 1/2 inch. These springs are made of a material, or plated with a material not affected by the cardiac jelly which lines a box pressed over the spring-covered side of the electrode while standing by for use at an unknown date.

In a laboratory it is easy to provide a circuit which shall be constantly alive with a capacity adequate for the step-up transformer which is to supply 5 amperes at 500 volts. Since the primary will require about 10 amperes at 240 volts, the control should be by means of a *DP* contactor with a 120-volt coil, operated by a timer which can be set for any value of time from 1/10 to 2 seconds' application of the defibrillating current.

Any further information relative to the construction of countershock equipment will be appreciated by the writer.

Charles F. Dalziel (University of California, Berkeley, Calif.): This paper is destined to be a bench mark in countershock resuscitation for human victims of electric shock accidents. Although the paper is largely confined to a presentation of experimental results obtained on dogs, it is evident that the authors consider that practical application to human beings is in the immediate offing. It is therefore desirable that the paper lay a proper foundation for both electrical techniques and legal technicalities.

It is only natural to anticipate that application of defibrillating shocks to human victims by laymen in the field will be both successful and unsuccessful. In the unfortunate event of failure the question is sure to be asked: "Which shock—the accidental shock or the defibrillating shock—was the responsible cause of death?" The authors' statement to the effect that with chest electrodes employing a single continuous pulse of 60-cycle a-c resuscitation current the chance of causing accidental death is less than one in 1,000 may be questioned on the basis of the experimental evidence contained in the paper. Elaboration of this conclusion might be exceedingly valuable.

The minimum shock likely to cause ventricular fibrillation is of great importance to the American Standards Association Sectional Committee on Electric Fences. Attempts are currently under way to develop satisfactory criteria for specifying the maximum allowable output from electric fence controllers. Publication of minium observed values of energy, current, voltage, and shock duration just producing ventricular fibrillation for both 60-cycle a-c and for capacitor discharges with electrodes placed on the surface of the body with the chest closed would be greatly appreciated by all of us working on this problem.

It is generally felt that translation of results obtained on animals to human beings is at most conjectural, and it would be enlightening for the authors to discuss this phase of the problem with special regard to closed-chest conditions. In the past it has been generally believed that the shock intensity required to stimulate the heart is roughly proportional to both body weight and heart weight. On this basis it would seem that the defibrillating current for man might be two to three times the values reported. Such currents might be destructive to tissues, and the corresponding voltages hazardous to the operator. On the other hand, even if no adjustment for weight is made, it would appear that the fibrillating threshold values (obtained from conversation and correspondence with the senior author) are so much in excess of the output from commercial intermittent electric fence controllers that the hazard from a single shock from these devices would appear to be entirely negligible. This leads to the possible argument that a material increase in the allowable output would be justified to increase the effectiveness of these devices, and that safety can be virtually assured by simply increasing the off period between successive shocks so as to reduce to the vanishing point the probability of a 2-year-old child ever being subjected to what the authors term serial shocks.

The authors are to be complimented on their persistence and time-consuming efforts to find the best possible solution to this most difficult and important problem. Undoubtedly counter electric shock is the most promising development in resuscitation for victims of electric shock accidents since the development of methods of artificial respiration.

Livingston P. Ferris (Ashton Plantation, Lecompte, La.): After a lapse of some years, it is good to have further experimental data concerning the effects of electric shock upon the heart, particularly its benign effect in reviving the heart from ventricular fibrillation arising from accidental electric shocks and, in rare instances, during surgery.

As a member some years ago of the Safety Committee, I urged renewed research along these lines as the only hope for substantial improvement in our record of resuscitation from accidental electric shocks. The author would agree, I believe, that these urgings had some influence on the initiation of the investigations reported on today. Therefore, it is with regret that I am not present to participate personally in this discussion.

With reference to the experiments on sheep mentioned in the author's fifth paragraph, the 3,000 volts was open-circuit before connection to the animal. Our power supply was heavily overloaded and regulation very poor, so the voltage across the animal dropped to about 900. This voltage is of interest only in estimating power supply requirements. Current alone is the significant measure of the shock. Fig. 17 of reference 5 of the paper gives a complete oscillographic record of a typical defibrillation test including before and after cardiograms, shock, currents, and voltages.

The Kouwenhoven-Milnor tests were all carried out on dogs weighing from 8 to 20 kilograms. Our tests were made on seven species of animals ranging in weight from about 1 to 100 kilograms. Our objective was to determine the relation of threshold fibrillating (not defibrillating) current to body weight and heart weight and to embrace the body weight of man. Figs. 4 and 5 (see reference 5 of the paper) show the results. A more than two-to-one difference in fibrillating current for sheep and dogs is indicated. We did not study the effect of body weight of different species on defibrillating current because our study was primarily directed at determining danger limits of current, and we could not carry the study of defibrillation nearly as far as desired. In the absence of contrary experimental evidence it would seem reasonable to expect that defibrillating as well as fibrillating current would depend to some extent upon body weight of the species of animal. The main point I wish to make on the authors' paper is that their defibrillating current for dogs should not be assumed optimum for man, and that further animal experimentation should be carried out to determine the effect of body weight. Before settling upon a value of current for reliable defibrillation of the human heart, further tests are in order on animals as large as sheep. While our study proved that 25 amperes of 60-cycle current for 1/10 second was effective for defibrillating the sheep heart, I hope that the optimum current will be less, perhaps much less. It is important to find out, and there is no way but by experiment.

Further tests should also explore the effect of duration of the defibrillating shock. There is certainly no advantage in prolonging the defibrillating shock more than necessary. I have been of the opinion that defibrillation required only the arresting of all muscular activity in the heart for some minimum time by a current sufficiently strong to overpower the disorganized forces acting on the individual fibers, then their simultaneous release to resume their natural tendency for co-ordinated action. If this be a true picture, it is a threshold current we must exceed for reliable defibrillation, rather than the prolongation or repetition of shock. The defibrillating shocks used and proposed by the authors seem much too long. If there is evidence that a lower current of longer duration can accomplish what a high short-duration shock does, the longer duration may be preferred because of the reduced power requirements. I do not see such evidence in the present paper.

The authors report increasing the duration of the defibrillating pulse with the duration of the preceding fibrillation, 1 second of pulse per minute of fibrillation. What evidence is there that increased duration of fibrillation requires a longer defibrillating pulse? Dr. King, one of my associates in the Columbia-Bell Laboratories studies, advises that he sees no physiological basis for such a relationship.

In further studies to determine the optimum characteristics of a defibrillating shock for man I should like to see the frequency of the current included, though I regard this as less important than other factors. But should we have to build special generators for field administration of defibrillating shocks, we might as well build them for the optimum frequency, if there is a substantial advantage to be gained over the common standard of 60 cycles.

The authors did not obtain encouraging results with capacitor discharges. There are so many circuit parameters that perhaps the right ones have been missed. The advantage of the capacitor discharge method, allowing the required energy to be stored slowly from low-powered circuits and discharged rapidly, may be great enough to warrant more thorough investigation before final discard. In view of the discouraging results thus far obtained, it seems desirable to pursue first the a-c method to its optimum characteristics. If the a-c power requirements turn out to be much lower than expected, then this method may be preferred for simplicity over the capacitor discharge method.

The authors report tests on what they term "serial defibrillation," a series of five or six short shocks of about 1/10 second duration occurring at intervals of about 1 second. They do not recommend it but report some hospitals using this method. I can see no reason for or advantage of "serial defibrillation" over a single pulse which may be repeated if observation shows failure. In principle, serial defibrillation seems analogous to interrupting artificial respiration to give the lungs a rest. Should one of the early pulses succeed in stopping the fibrillation, there would be some danger that later pulses would start it again. Furthermore, if we consider the use of defibrillation equipment in the accident field without the precaution of a cardiographic check, then repetition of the pulses would increase the danger of causing fibrillation when it did not preexist. This is due to the mathematical increases in probability that one of the series of pulses will strike in the sensitive T-wave (partial refractory) phase of the cardiac cycle. In this connection reference should be made to Figs. 13 and 15 of reference 5 of the paper. I believe this explains the danger reported by the authors of "serial defibrillation" shock applied to normal hearts.

The improbability of a random short shock of 1/18 second or less occurring during the short sensitive phase of the heart cycle is an important reason for trying to limit the defibrillating shock to as short a duration as possible. This is particularly true for accident cases in the field where electrocardiographic checks of heart condition seem extremely difficult. This advantage combined with the decrease in liability of fibrillation with high currents might warrant consideration of countershocks being given by well-trained personnel without check of heart by cardiograph. However, the danger of setting a normal heart in fibrillation should first be more thoroughly studied by further tests, once the optimum defibrillating shock is found.

In operating-room use of defibrillating apparatus, the misapplication of defibrillating shocks to a normally beating heart should present no problem. The subject is in expert hands, under constant observation and it should not be too difficult to add an electrocardiograph to normal equipment. Defibrillating equipment could be built-in or portable. It should be provided with safety switches and signals for protection of patient and operating personnel, and sparkproof for prevention of explosions.

When nearly 20 years ago we cautiously suggested the use of countershock apparatus in accident cases with the precaution of electrocardiographic checks on the heart, I remember the rather emphatic opposition of some resuscitation experts. This may have set back necessary studies many years. Fortunately, studies are under way again. There is much still to be investigated and I hope the fundamental studies will be continued until safe, reliable defibrillating equipment and practices are available for field cases and operating rooms. With continued close co-operation between the medical and engineering professions, I am confident that this objective can be attained.

Donald A. Picken (Ministry of Labour and National Service, Liverpool, England): First, dealing with details of the paper, it is stated that the only known method of arresting fibrillation is by induction of complete tetany. There are many ways in which fibrillation can be stopped, for example, by injection of common materials, such as ammonium chloride. The difficulty is that these materials have to be removed from the heart by irrigation. Fischer and Fröhlicher have done a great deal of work on chemical control of fibrillation and they recommend the injection of acetyl choline which, by producing a temporary nerve block, brings fibrillation to a stop. In a short time, the acetyl choline is hydrolized into products which act as stimulants. This method has been well proved by experiments.

All the information upon which the article is based is apparently deduced from experiments on dogs. The validity of comparison between dogs and human beings is extremely doubtful. Experiments which have been carried out on muscles and nerves from different animals respond in a widely different manner and I suggest that much more information is necessary on the validity of comparisons between the subjects and human beings before the results can be and human beings before the results can be of value. Much information on the effects of electric current on animals has been proved not valid for humans.

It is stated in the paper that when ventricular fibrillation obtains, blood circulation ceases and death ensues. It is not always true that blood circulation entirely ceases. In some cases over and above the fibrillating rhythm a weak heart beat of low frequency has been detected which would produce some blood circulation. Further, Jellinek suggests that fibrillation itself may be spontaneously eliminated, though not with the lower order of animals. It does occur with monkeys.

The methods suggested, while they might produce the elimination of fibrillation, are likely to have serious side effects. My investigations into fatal accidents suggest that the role of fibrillation is overemphasized and that a considerable number of deaths are due to nerve blocks rather than to fibrillation.

The possibility of causing a nerve block by currents of the magnitude suggested in the region of the thorax is considerable and it should be adopted only as a last resort. The aim of the first-aider in cases of electric shock should be to ventilate the lungs and to cause blood circulation. The use of high-frequency currents to stimulate heart beats has been tried, but the general application of current is difficult. Much simpler techniques are essential for any widespread success, and the method should deal much more generally with the effects of electric shock on human beings.

At present work is being carried out on the efficacy of the rocking-stretcher technique not only as a ventilator for the lungs, for which it is certainly adequate, but also as a means for inducing blood circulation. It has been established that a considerable degree of blood circulation does result from application of the rocking-stretcher technique, even when the heart is stationary.

Work on electricity and humans, along the lines of that being done by Djourno in Paris and that already done by Fröhlicher in Zurich is, in my opinion, essential.

The recommendation made by Djourno is one worthy of attention: when a patient is unconscious from electric shock a hollow needle should be inserted into the wall of the heart. If the heart is beating feebly this can be used to inject a heart stimulant. If the heart is fibrillating it can be used to control the fibrillation either chemically by the use of acetyl choline or electrically by the induction of tetany. This method is much less hazardous from the point of view of side effects than is the external application.

W. B. Kouwenhoven and **W. R. Milnor**: The electrode-mounting described by Mr. Radley is an interesting one and should be tried. His arrangement with one electrode on the shoulder and the other on the abdomen involves a long current path and this may require an increase in voltage to produce defibrillation.

We do not recommend repeated applications of the defibrillation current. In cases where an electrocardiograph is available and the heart is not defibrillated by the initial application, a second application should be tried. This, however, is not true in the field.

To provide good contact between the electrode surface and the body, we are planning to insert a plastic sponge about 1 inch thick between a backing piece of insulating material and the electrode. A spiral groove will be cut in the copper electrode, which will be glued to the plastic sponge. When cardiac jelly is used it is not necessary to cover the electrode surface with cloth.

It is of the utmost importance that artificial respiration be started as soon as possible and that it be maintained continuously, except during brief periods required for the application of the defibrillating current.

Professor Dalziel is correct in his statement that the application of a-c defibrillation to humans by doctors and laymen will result in failures as well as successes. We feel that the closed chest method of defibrillation should be first tried in hospitals. It should be remembered that there are many more cases of ventricular fibrillation annually in hospitals than there are in the field.

Both Mr. Ferris and Mr. Dalziel question the use of dogs as the experimental animal in this study. The dog was selected because of the large body of evidence from different kinds of medical research showing the cardiovascular physiology of the dog is analogous in many ways to that of the human heart. We are not convinced that body weight itself is an important factor in electric defibrillation. It seems more probable that the current passing through the heart, which would be determined by the voltage applied and the resistance of the pathway, is the most important factor.

In open-chest defibrillation the same voltage is used for infants and adults. The only change made is in the size of the electrodes placed on the heart. For infants the electrode diameter is 1.125 and for adults 1.75 inches. In dogs ranging from 7 to 20 kilograms, no difference was found in the response to defibrillating shocks.

In the inital stages of this work with the electrodes on the opposite sides of the chest, we applied the defibrillating current for 1 second to a heart that had been in fibrillation for 1 minute. Using the hand electrodes, we have been studying the effect of reducing the duration of the current flow, and find that durations of from 0.3 to 0.5 second are ample to bring the twitching heart muscles to rest after 2 minutes in fibrillation.

Many authors, including Mr. Ferris, have reported that the sensitivity of the heart to electric shock varies during the cycle. In the authors' study of the effects of capacitor discharges, it was recognized that if the sensitive phase was known, the shocks could be timed to pass through the dog during that period and that the time devoted to the study could be shortened. The current pathway through the animals was from right foreleg to left foreleg. One hundred and forty one discharges were sent through the bodies of 18 dogs without finding any correlation between the energy in the discharge, its position in the heart cycle, and the occurrence of fibrillation. Under the conditions of our experiments, therefore, no sensitive phase could be demonstrated.

We have only studied two frequencies as sources of defibrillating current, namely 60 and 400 cycles. The higher frequency current has been studied on 22 animals and is not a satisfactory source of supply for this purpose.

It is our opinion that defibrillating equipment should be designed to use the standard commercial frequencies because of their availability. A convenient and inexpensive source of defibrillating current is a 2-kva low-impedance transformer with primary voltage taps ranging from 120–2,400 volts.

The authors agree with Mr. Ferris, as stated in the paper, that a capacitor defibrillator would possess advantages. During 3 years we carried on intensive experimental capacitor studies, commenced in 1949, and we are still trying out new ideas and suggestions. Unfortunately we were not successful in developing an effective capacitor circuit for defibrillation.

Mr. Picken states that there are many ways in which fibrillation may be arrested. Kay,[1] working on drugs as a means of stopping fibrillation, found them to be ineffective. Fischer and Fröhlicher carried out their experiments with acetyl choline on the isolated, perfused heart. We have experimented with this drug on dogs with their hearts in place and their circulatory systems intact. In none of our experiments, under these conditions, were we able to stop fibrillation with acetyl choline.

While it is not possible to transfer directly the results of animal experimentation to humans, there exists a mass of medical evidence showing that the cardiovascular system of the dog is analogous to that of man. For example, the same voltages, currents, and circuit conditions, which in 1933 were found to be effective in defibrillating the dogs' hearts[2] are used today in hospitals on human hearts. When the human heart fibrillates the effective circulation of the blood ceases, and unless the circulation is promptly restored death will ensue.

We have experimented with monkeys and have confirmed Jellinek's finding that the monkey's heart often recovers spontaneously from fibrillation. In general this is true of animals with small hearts.

We have not had a single instance of the passage of the defibrillating current through the current pathway that we are using, causing any side effects. The method has been successfully applied to one human being whose heart went into fibrillation while undergoing anesthesia.

It is impossible to state accurately how many cases of ventricular fibrillation occur annually as the results of electric shocks. The Accident Prevention Committee of the Edison Electric Institute report that among utility employees there are approximately 50 electric shock deaths each year, where artificial respiration was started with the promptness that should have ensured a successful recovery, but failed.

The rocking-stretcher technique mentioned by Mr. Picken, should produce some circulation of the blood. The needle technique is an interesting suggestion. We suggest, however, that the shaft of the needle be covered with insulation, except for a small area near the end. Then if the needle is used as one electrode the current will be more closely confined to the heart.

The Use of Probability in the Design and Operation of Secondary Network Systems

N. M. NEAGLE
ASSOCIATE MEMBER AIEE

D. R. NELSON
ASSOCIATE MEMBER AIEE

THE PURPOSE of this paper is to present a method of investigating the probability of the various types of outages which can occur on a secondary network system. Briefly, the results may be used in two ways: 1. To determine the principal causes of these outages. 2. To compare the effect of changes in operating procedure and system design on these outages.

Conclusions

With the aid of probability, it is possible to calculate the probability of occurrence of secondary network equipment outages, their frequency, and their duration. The data needed for a probability study are the individual network equipment outage rates. If these data are not available for the system to be studied, industry records of the equipment outage rates may be used. Placing these data in the equations shown will enable the system designer to calculate the probability of occurrence of system outages for the present and future systems.

Description of System

The secondary network is a low-voltage a-c distribution system. It is principally an underground system used to feed commercial areas; see Fig. 1. All loads, large and small, are connected to a common 120/208-volt grid supplied with power through judiciously located network transformers. These transformers are connected to one of two or more primary feeders which are so interlaced that no two adjacent transformers are supplied from the same feeder. On the secondary of the transformer is a network protector containing a fuse, an air circuit breaker and a relay. The relay operates the breaker by tripping it on reverse power flow and closing it when the voltage on the transformer secondary is greater than that on the grid. This network unit (transformer and protector) is located in a vault either singly or with several other units. Where several units are located in one vault it is called a multiunit vault.

The network system provides a high order of service to all customers, because all the loads and all the network units are connected to a common grid. The outage of any network unit means that its load is transferred to the remaining units. Because of the impedance of the interconnecting grid cables the principal portion of this load would be carried by the adjacent units. In a multiunit vault or spot network vault these adjacent units would be the remaining energized units in this vault.

System Design

The system must be designed with a knowledge of the outages that may reasonably occur on the system and the ability of the remaining energized units to carry the total load. In this the system designer has two distinct problems: 1. of supplying power to the system, and 2. of supplying power to the grid at the various load locations.

The problem of supplying power to the system is concerned with the distribution of large amounts of power over the primary feeders to the many network units. The designer must determine how many feeders are required to supply the load for all reasonable operating conditions. In this case a knowledge of the probability of feeder outages is required.

The second problem is to transform this power from the primary feeders to the grid. In multiunit vaults several network units are solidly tied together to one bus. The problem here is to provide adequate transformer capacity to carry the load on this bus during normal operating conditions. Hence a knowledge of network unit outages is important.

Definition of Terms

A single-contingency outage is defined as the outage of one unit of a group of units. A double-contingency outage is the simultaneous outage of two units in a group of units, and a triple-contingency outage is the simultaneous outage of three units in a group of units. The term outage as employed here is intended to mean the failure of a piece or pieces of equipment to carry its share of the system load.

Approach to the Problem

The explanation of the use of probability to investigate network system outages will be mainly accomplished with examples. These examples are not intended to be typical for all systems, but are used only to show how to apply the principles of probability to determine the network system outages.

Probability

The application of the theory of probability involves the determination of the chance of an event occurring in a given manner. Likewise, the theory of probability can be applied to determine the chance of two or more events occurring in

---

Paper 55-160, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 20, 1954; made available for printing December 3, 1954.

N. M. Neagle and D. R. Nelson are with the General Electric Company, Schenectady, N. Y.

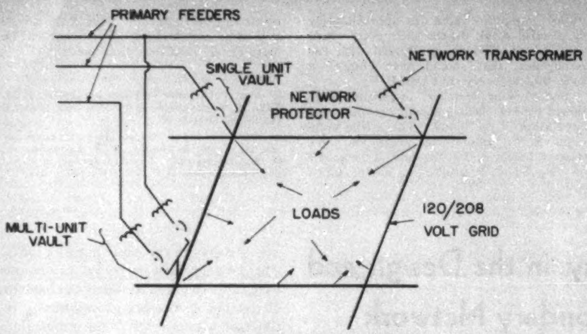

Fig. 1. The secondary network system

a particular combination, if the probability of the individual events is known. Two important fundamental theories of probability are: 1. The total probability of mutually exclusive events is equal to the sum of the individual total probabilities. 2. The probability of two or more independent events occurring simultaneously is the product of the individual probability.

Mutually exclusive events are events that cannot occur at the same time, whereas independent events are events that can occur simultaneously.

PROBABILITY OF INDIVIDUAL EVENTS

Determination of the probability of a single event occurring is rather simple. If the probability of an event occurring is P, then

$$P=\frac{\text{number of times the event occurs}}{\text{number of times the event occurs plus the number of times the event could occur but does not occur}}$$

Assuming that an event occurs 10 days during a year and will not occur the remaining 355 days of a year, then the probability of its occurrence on any particular day will be $P=10/(10+355)$ which equals 10/365 which equals 0.0274.

The first step in a study of the probability of system or vault outages is to determine the probability of individual equipment outages which will lead to vault or system outages. There are three types of individual outages that will affect the network unit (cause disconnection of the network transformer from the grid). These are:

1. Network protector failures.
2. Feeder faults.
3. Feeder maintenance.

1. Network protector failures may be of several different types. The only types of concern here are those which leave the protector open when it should be closed; i.e., leave the network protector's transformer disconnected from the system. Using data published by the Edison Electric Institute,[1] the probability of network protector outages can be determined as follows. For the period 1944 to 1946 the Edison Electric Institute report[2] on a-c network operations records 0.045 failures per protector per year. This includes failures to open and failures to close, but not fuse blowings. Of this total 64.9 per cent (%) were failures to close, making

$$0.649\times0.045=0.0292 \text{ failures to close per protector per year}$$

For use here these failure data must be placed on a time base. To do this the means of detection must be examined. Because of the inherent interconnecting load-supporting function of the network grid it is assumed that only a vault inspection or a supervisory system would determine whether a protector is open when it should be closed. Where supervisory systems are not employed the burden of detection falls upon individual inspections. If these occur once a year an average outage period for each failure might be 6 months. The outage rates would then be

$$\text{Failure to close}=0.0292\times\frac{365}{2}\text{ days}$$
$$=5.34 \text{ days per protector per year.}$$

The associated probability of any network protector being out of service at any time would therefore be

$$P_1=\frac{5.34 \text{ days per year}}{365 \text{ days per year}}=0.0146$$

If detection measures were conducted every 6 months, this probability would be reduced by 50%. The frequency of inspection is therefore the principal factor in the probability of network protector outages.

2. Faults can occur on a feeder with the failure of a cable, a joint, or a transformer. This produces a primary feeder outage by the removal of the feeder from the system by its associated protective equipment. The feeder failure rate can be determined from individual failure rates of feeder components as published in Edison Electric Institute reports. If a primary feeder were 2 miles long, had 30 joints and was connected to 14 network transformers, its total failure rate would be:

Cable failures per year $=0.068\times2$ miles $=$	0.136
Joint failures per year $=0.005\times30$ joints $=$	0.150
Transformer failures per year $=0.00274\times14$ transformers $=$	0.038
Total failures per feeder per year $=$	0.324

Assuming that approximately 2 days would be required to locate and clear the fault and return the feeder to service, the days of outage per year would be $0.324\times2=0.648$ days per year. The probability of any feeder being out of service because of fault at any time during the year would then be

$$P_2=\frac{0.648 \text{ days per year}}{365 \text{ days per year}}=0.00178$$

3. Feeder maintenance outage is the planned removal of the entire primary feeder and its associated units from service for the purpose of maintenance work. Assuming that the total time a feeder will be out of service for maintenance during any one year is 2 days, the probability of any particular feeder being out of service for maintenance at any time during the year will be

$$P_3=\frac{2 \text{ days per year}}{365 \text{ days per year}}=0.00548$$

PROBABILITY OF SEVERAL EVENTS

Knowing the individual probabilities; i.e., P_1 probability of network protector outages, P_2 probability of feeder fault outages, and P_3 probability of feeder maintenance outages, it is now possible to determine the probability of outages in the vault of N units (see Fig. 2) as follows:

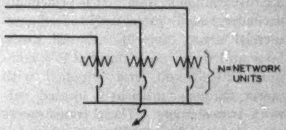

Fig. 2. N unit network vault

P_1 = probability of network protector being out of service
P_2 = probability of a primary feeder being out due to a fault
P_3 = probability of a primary feeder being out due to maintenance
P_A = probability of a network unit being out of service $P_A = P_1 + P_2 + P_3$
P_G = probability of all N units being in service
P_M = probability of M out of N units being out of service
P_N = probability of all N units being out of service
$P_G = (1-P_A)^N$
$P_M = (P_A)^M(1-P_A)^{N-M} N^C N-M$
$P_N = (P_A)^N$

P_1, P_2 and P_3 are mutually exclusive (see the Appendix) in that only one can occur at a time. Therefore, the total probability of a network unit being out of service in a vault is simply the sum of P_1, P_2 and P_3 to give P_A, the probability that one network unit in a vault will be out of service. Likewise, $1-P_A$ is the probability of one network unit being good or in service.

The probability of having two network units out of service in a vault is an independent event, as each can occur simultaneously. Therefore the probability of having two network units in service is $(1-P_A)$ $(1-P_A)$. . .while the probability of having two network units out of service in a vault is (P_A) (P_A). . . Based on this, equations can be presented which will express the probability that an outage will or will not occur in a given vault. For example, assume N units are in the vault and it is desired to know the probability that all units are good. The probability that all units are good is

$$P_G = (1-P_A)^N$$

The probability that M out of N units will be out of service is

$$P_M = (P_A)^M(1-P_A)^{N-M} N^C N-M$$

The combination factor $N^C N-M$ simply accounts for the number of ways in which this particular combination of outage can occur (see equation in the Appendix). This equation can be carried on until the probability of all units being out of service would be

$$P_N = (P_A)^N$$

These general equations are presented at the beginning of this section.

Examples

THE 4-UNIT VAULT

The easiest way to describe the use of the probability equations is with the aid of examples. First, assume that it is desired to determine the probability of the various outages in a 4-unit vault. The equipment in this vault has the values of individual probability determined earlier ($P_1 = 0.0146$, $P_2 = 0.00178$ and $P_3 = 0.00548$).

The types of outages, their probability equations, and their calculated values are as follows:

$P_1 = 0.01460$ = probability of network protector being out of service
$P_2 = 0.00178$ = probability of a primary feeder being out as result of a fault
$P_3 = 0.00548$ = probability of a primary feeder being out due to maintenance

$P_A = 0.02186$ = probability of a network unit being out of service
P_G = (all good) $= (1-P_A)^4$ $= 0.91537$
P_S = (one out) $= (P_A)(1-P_A)^3 {}_4C_1$ $= 0.08183$
P_D = (two out) $= (P_A)^2(1-P_A)^2 {}_4C_2$ $= 0.00274$
P_T = (three out) $= (P_A)^3(1-P_A) {}_4C_3$ $= 0.00004$
P_4 = (four out) $= (P_A)^4$ $= 0.00000$

0.99998

The probability of all combinations should equal 1.0.

The probability of having at least three units in service is:

$P_G = 0.91537$
$P_S = 0.08183$

0.99720 = probability that least three units are in service

The probability of having at least two units in service is:

$P_G = 0.91537$
$P_S = 0.08183$
$P_D = 0.00274$

0.99994 = probability that at least two units are in service

The value of the probability for each event occurring is a number less than 1. One way to consider these numbers is that they tell the per cent of the time a certain event will occur. For example, P_G all good, equals 0.91537 or, on the average, all the network units in this vault will be good 91.537 per cent of the time. Likewise, 8.463% of the time, one or more units will be out of service. Adding P_G and P_S evaluates the time that at least three units will be in service. Similarly, adding P_G, P_S, and P_D determines the time that at least two units will be in service. These values from the foregoing equations are 99.72% and 99.994% of the time respectively.

THE 4-FEEDER SYSTEM

Suppose it were desired to determine the availability of feeders to transmit power to the grid or, conversely, to determine the probability of feeder outages, particularly multiple contingency outages. Since a network protector outage will not disconnect a complete feeder from a system, its occurrence can be ignored for this investigation. If the system to be examined had four feeders, the associated probabilities of outage, employing P_2 and P_3 as defined earlier, would be as indicated as follows:

$P_2 = 0.00178$ = probability of a primary feeder being out because of a fault
$P_3 = 0.00548$ = probability of a primary feeder being out due to maintenance

$P_A = 0.00726$ = probability of a network unit being out of service
P_G = (all good) $= (1-P_A)^4$ $= 0.971278$
P_S = (one out) $= (1-P_A)^3(P_A) {}_4C_1$ $= 0.028404$
P_D = (two out) $= (1-P_A)^2(P_A)^2 {}_4C_2$ $= 0.000318$
P_T = (three out) $= (1-P_A)(P_A)^3 {}_4C_3$ $= 0.000000$
P_4 = (four out) $= (P_A)^4$ $= 0.000000$

1.000000

The probability that at least three feeders are in service is calculated as follows:

$P_G = 0.971278$
$P_S = 0.028404$

0.999682 = probability that at least three feeders are in service

In comparing the results of calculation on a 4-unit vault and the results on a 4-feeder system, it is obvious that the values of probability of outages have been considerably reduced. Outages are more likely in the vault because of the value of the P_1 probability of a network protector being out of service. The comparison indicates the need for a higher ratio of transformer capacity to load than feeder capacity to load. This is not the whole story, as an isolated outage confined in one vault on the system is not as serious as an outage of two whole feeders on a system.

VARIATION OF THE PROTECTOR OUTAGE TIME

The principal reason for the protector as a cause for a double-contingency outage is the duration of its outage following its failure to close. Assuming that the protector is going to be supervised so that its average outage time will not be 6 months but will be the same average duration of 2 days as that for a feeder maintenance and a feeder fault, then the probability P_1 (protector outage) is reduced from 0.0146 to 0.00016. This will reduce the value of P_A (probability of a feeder outage) from

0.02186 to 0.00742. The results of calculations in the 4-unit vault using the reduced protector outage time are:

$P_1 = 0.00016$ = probability of network protector being out of service
$P_2 = 0.00178$ = probability of a primary feeder being out because of a fault
$P_3 = 0.00548$ = probability of a primary feeder being out due to maintenance
$P_A = 0.00742$ = probability of a network unit being out of service
P_G = (all good) $= (1-P_A)^4 = 0.97065$
P_S = (one out) $= (1-P_A)^3(P_A)\,{}_4C_1 = 0.02906$
P_D = (two out) $= (1-P_A)^2(P_A)^2\,{}_4C_2 = 0.00033$
P_T = (three out) $= (1-P_A)(P_A)^3\,{}_4C_3 = 0.00000$
P_4 (four out) $= (P_A)^4 = 0.00000$
$\overline{}$
1.00004

The probability of having at least three units in service is as follows:

$P_G = 0.97065$
$P_S = 0.02906$
$\overline{}$
0.99971 = probability that at least three feeders are in service

Now, all the units are good on the average 97.065 as compared to 91.537% of the time from the calculation of the 4-unit vault. The probability of having at least three units in service in this vault is now 0.99971, which is about the same as the probability of having only two units in service, or 0.99994 in the 4-unit vault.

The 3-Unit Vault with Protector Outage Time Reduced to 2 Days

An interesting comparison can now be made using the reduced protector outage time of 2 days in a 3-unit vault as compared to the 6-month protector outage in a 4-unit vault. Following are the probabilities of the contingency outages in a three-unit vault:

$P_1 = 0.00016$ = probability of network protector being out of service
$P_2 = 0.00178$ = probability of a primary feeder being out due to a fault
$P_3 = 0.00548$ = probability of a primary feeder being out due to maintenance
$\overline{}$
$P_A = 0.00742$ = probability of a network unit being out of service
P_G = (all good) $= (1-P_A)^3 = 0.97791$
P_S = (one out) $= (1-P_A)^2(P_A)\,{}_3C_1 = 0.02193$
P_D = (two out) $= (1-P_A)(P_A)^2\,{}_3C_2 = 0.00016$
P_T = (three out) $= (P_A)^3 = 0.00000$
$\overline{}$
1.00000

The probability of having at least two units in service is as follows:

$P_G = 0.97791$
$P_S = 0.02193$
$\overline{}$
0.99984 = probability that at least two units are in service

The probability of having at least two in service is 0.99984, which is about the same probability, 0.99994, of having two units in service in a 4-unit vault. Thus the additional supervision of the protector in reducing its average outage time from 6 months to 2 days practically has reduced the need of having the fourth transformer in this multinetwork vault.

No-Feeder Maintenance

Up to this point no restriction has been placed on the occurrence of feeder maintenance. The equations have allowed feeder maintenance to occur in a similar fashion to feeder faults. As all four feeders can be taken out for faults, so the equations have allowed all four feeders to be taken out for maintenance. This is not the case in practice, as most systems will not take a feeder out of service for maintenance during peak load periods because this outage might lead to a double-contingency outage during a critical period.

The probabilities calculated in the following assume that a feeder will never be taken out of service for maintenance. This is the other extreme operating condition as compared to unlimited maintenance. Comparing the results of the 4-unit vault calculation and the results of no-feeder maintenance, shows that there has been a reduction in the total probability of contingency outage of only 0.02062, assuming that no feeders will be taken out of service in a 4-unit vault for maintenance purposes.

$P_1 = 0.01460$ = probability of network protector being out of service
$P_2 = 0.00178$ = probability of a primary feeder being out due to a fault
$\overline{}$
$P_A = 0.01638$ = probability of a network unit being out of service
P_G = (all good) $= (1-P_A)^4 = 0.93599 \quad 0.91537$
P_S = (one out) $= (1-P_A)^3(P_A)\,{}_4C_1 = 0.06245 \quad 0.08183$
P_D = (two out) $= (1-P_A)^2(P_A)^2\,{}_4C_2 = 0.00156 \quad 0.00274$
P_T = (three out) $= (1-P_A)(P_A)^3\,{}_4C_3 = 0.00001 \quad 0.00004$
P_4 = (four out) $= P_A^4 = 0.00000 \quad 0.00000$
$\overline{} \quad \overline{}$
$1.00001 \quad 0.99998$

The figures in the last column are from the calculations on the 4-unit vault.

$P_G = 0.93599$ = (all good from above for no maintenance)
$P_G = 0.91537$ = (four-unit vault calculations all good for unrestricted maintenance)
$\overline{}$
0.02062 = reduction in probability of outages with no feeder maintenance

Limited Feeder Maintenance

A more realistic approach is to assume that a feeder will be taken out of service for maintenance if no other feeder is out of service due to a fault or maintenance. This places a restriction on maintenance outages that can occur. For example, some double-contingency outages are caused by a feeder fault (P_2) and a feeder maintenance outage (P_3). If a feeder is not removed from service following a feeder fault, then P_2 (probability of a feeder fault) will not be followed by P_3 (probability of a feeder maintenance). But P_3 (feeder maintenance) can be followed by P_2 (feeder fault) to lead to a double-contingency outage. Thus, with this type of restriction on feeder maintenance certain of the combinations leading to the various degrees of contingency outages must be corrected.

For example, in order to correct the probability figures of the 4-unit vault calculation to conform to the new maintenance restriction, the terms (P_A) must be expanded as is accomplished in limited feeder maintenance. Certain terms must then be moved from one contingency to another, according to the effect of this maintenance restriction. The terms which must be moved are underscored in the following.

The terms for the outages expanded are:

$$P_G = (1-P_A)^4 = (1-P_A)^4$$

$$P_S = P_A(1-P_A)^3\,{}_4C_1 = (P_1+P_2+P_3)(1-P_A)^3\,{}_4C_1$$

$$P_D = P_A^2(1-P_A)^2\,{}_4C_2 = (P_1^2+P_2^2+\underline{P_3^2}+2P_1P_2+\underline{2P_3P_2}+2P_1P_3)(1-P_A)^2\,{}_4C_2$$

$$P_T = P_A^3(1-P_A)\,{}_4C_3 = (P_1^3+P_2^3+\underline{P_3^3}+3P_1^2P_3+3P_1^2P_2+\underline{3P_2^2}P_1+\underline{3P_2^2}P_3+\underline{3P_3^2P_1}+\underline{3P_3^2}P_2+\underline{6P_1P_2P_3})(1-P_A)\,{}_4C_3$$

$$P_4 = P_A = \text{(not of value)}$$

Terms to be added to P_S are:

$$\text{From } P_D = \left[P_3^2+\frac{P_3}{P_2+P_3}(2P_3P_2)\right]\times(1-P_A)^2\,{}_4C_2 = 0.00026$$

$$\text{From } P_T = \left[P_3^3+\frac{P_3}{P_1+P_2+P_3}(3P_3^2P_2)\right]\times(1-P_A)\,{}_4C_3 = 0.00000$$

Terms to be added to P_D:

$$\text{From } P_T = \left[\frac{P_2+P_3}{P_1+P_2+P_3}(3P_3^2P_1)+3P_3^2P_1+\frac{P_1+P_3}{P_1+P_3+P_2}(3P_3^2P_2)+\frac{P_3}{P_2+P_3}(6P_1P_2P_3)\right](1-P_A)\,{}_4C_3 = 0.00003$$

Values of 4-unit calculations corrected for the maintenance restrictions are as follows:

$$\begin{aligned}
P_G&=0.91537 &&=0.91537\\
P_S&=0.08183+0.00026 &&=0.08209\\
P_D&=0.00274+0.00003-0.00026 &&=0.00251\\
P_T&=0.00004-0.00003 &&=0.00001\\
P_4&= && \underline{0.00000}\\
& && 0.99998
\end{aligned}$$

For example, $(P_2)^2$ in P_D cannot occur as only one feeder will be taken out of service for maintenance at a time. So this term $(P_2)^2$ must be moved from P_D double-contingency outage to P_S single-contingency outage. The terms $2P_2P_3$ in P_D will not occur 100% as a double-contingency outage. If P_3 feeder fault occurs first, P_2 maintenance cannot occur. If P_2 occurs first, then P_3 can occur and lead to a double-contingency outage. Thus a portion of $2P_2P_3$ must be moved from P_D to P_S. This portion or fraction depends on the value of P_2 and P_3. As a double-contingency will not exist if P_3 occurs first, then $[P_2/(P_2+P_3)]$ $(2P_2P_3)$ is the portion of these terms to be subtracted from P_D and added to P_S. Other terms are handled in a similar fashion in the limited feeder maintenance calculation.

Interpretation of Results

As it has been pointed out, these probabilities can be expressed in terms of per cent of a year or years. From the calculation on a 4-feeder system the probability of a double-contingency outage is found to be 0.000318. Multiplying 0.000318 by 365 determines the average days outage per year

$$365(0.000318)=0.116070 \text{ day per year}$$

This term does not mean that there will be 0.11607 day of double-contingency outage each year but rather, on the average, this outage will occur 0.11607 day per year. For example, this might mean a double-contingency outage of 1.1607 days every 10 years or 11.607 days every 100 years. Obviously, if the double fault occurs only once every 100 years, this type of fault will not worry a system designer; whereas a fault of 0.11607 day (2 hours, 48 minutes) each year may be of long enough duration and occur frequently enough to be planned for by the system designer. Thus the frequency and duration of the probability of the faults is important to know. Using the 4-feeder system calculation as an example, the duration and frequency will be found.

INTERPRETATION OF SYSTEM FEEDER OUTAGES FROM 4-FEEDER SYSTEM CALCULATION

The 4-feeder system calculation consists only of feeder faults and feeder maintenance outage occurring on a 4-feeder system. Each of these individual outages P_2 and P_3 occurs for an average of 2 days' duration. When the individual outage durations are known the average duration of any contingency outage can also be determined. For the double contingency with each individual outage 2 days long the average double-contingency outage time will be 1 day long. This can be expressed as

$$\text{average duration of outage}=\frac{D_1\times D_2}{D_1+D_2}$$

where

D_1 = average outage duration of one of the failures

D_2 = average outage duration of the second failure

For the 4-feeder system calculation each duration P_2 and P_3 is 2 days and the average duration of a double-contingency outage is 1 day $(2\times 2)/(2+2)$. Dividing 0.11607 into this 1-day duration will determine the average years to obtain an average double-contingency outage of 1 day, or 1/0.11607, or 8.5 years. This means that for this 4-feeder system there will be a double-contingency outage of 1 day every 8.5 years. This same principle can be carried on into other examples to determine the average number of years between faults of a certain duration.

INTERPRETATION OF UNIT OUTAGES IN A 4-UNIT VAULT

Unfortunately the calculation on a 4-feeder system is by far the easiest to examine as only two individual faults (maintenance and feeder) each having a 2-day individual duration make up the duration of an average double-contingency fault. For the case of the vault examined for the 4-unit vault calculation there are six combinations which make up the total probability of the double-contingency outage time. Among the six combinations (see Appendix) there are three different average fault durations. Thus the total probability of a double-contingency outage (0.00274) is made up of several different durations. To examine each term, $(P_A)^2$ must be expanded as in the following interpretation of results.

$$P_D=(P_A)^2(1-P_A)^2{}_4C_2=\text{double contingency}$$
$$(P_A)^2=(P_1+P_2+P_3)^2$$
$$P_D=(P_A)^2(1-P_A)^2{}_4C_2=[P_1^2+P_2^2+P_3^2+2P_1P_2+2P_1P_3+2P_2P_3](1-P_A)^2{}_4C_2$$

The duration of the individual faults are as follows:

P_1 = protector outage average 6 months

P_2 = feeder maintenance outage average 2 days

P_3 = feeder failure outage average 2 days

The duration of the average double-contingency faults is:

1. $P_1P_1=\frac{6\times 6}{6+6}$ or $\frac{36}{12}=3$ months or 91 days

2. $\left.\begin{array}{r}P_2P_2=\\ P_3P_3=\\ 2P_2P_3=\end{array}\right\}\frac{2\times 2}{2+2}$ or $\frac{4}{4}=1$ day

3. $\left.\begin{array}{r}2P_1P_2=\\ 2P_1P_3=\end{array}\right\}\frac{90\times 2}{90+2}=\frac{180}{92}=1.96$ days

Probability of the three different double-contingency faults cause the total P_D.

1. $P_1^2(1-P_A)^2{}_4C_2$ $=0.00122$
2. $P_2P_2^2+2P_2P_3)(1-P_A)^2{}_4C_2$ $=0.00030$
3. $(2P_1P_2+P_1P_3)(1-P_A)^2{}_4C_2$ $=0.00122$

Years between the three different double-contingency faults are

1. $\frac{91}{0.00122\times(365)}=204$ years between double - contingency fault of 91 days' duration due to P_1P_1

2. $\frac{1}{0.00030\times(365)}=9.17$ years between double - contingency fault of 1 day's duration caused by $P_2P_2+P_3P_3+2P_2P_3$

3. $\frac{1.96}{0.00122\times(365)}=4.41$ years between double - contingency fault of 1.96 days' duration caused by $2P_1P_2+2P_1P_3$

The six combinations are listed under items 1, 2, and 3, and are made up of three different durations of faults, one of 91 days, one of 1 day, and one of 1.96 days. Solving for each of these individually the results are:

1 double-contingency fault of 91 days occurs every 204 years (due to P_1)

1 double-contingency fault of 1 day occurs every 9.17 years (due to P_2 and P_3)

1 double-contingency fault of 1.96 days occurs every 4.41 years (due to P_1, P_2, and P_3)

From this it can be seen that although the protectors themselves are major contributors to the double-contingency probability, these double contingencies caused by protectors are separated by many years and hence are not as important as some of the more frequent double-contingency faults. Of course, the protectors also contribute along with feeder faults $(2P_1P_3)$ and feeder maintenance $(2P_1P_2)$ to average 1.96 days of faults every 4.41 years.

Summary

Thus it is possible not only to calculate the probability of any contingency of faults on a network system or in a network vault, but also to obtain the average duration of these faults and the average years between their occurrence. Different systems or different operating procedures can thus be compared on the basis of reliability as well as economics.

The calculations have used the same probability of outage (P_A) for each primary feeder. In many systems some feeders have older equipment and may be exposed to more faults than new feeders with new equipment. Then it was assumed that these faults occur equally at any period of the day or night, or at peak load or light load. These assumptions were made in order to simplify the calculations.

It must be recognized that probability only expresses average conditions. It might take 1 year or 200 years to reach certain average conditions. Some checks have been made on an actual system, and it was found that the values obtained were reasonably consistent with what occurred on that system.

Appendix

An earlier paper[3] treated the faults P_1, P_2 and P_3 (individual outages) as independent events. After considerable discussion it appears that these individual probabilities may more properly be treated as mutual exclusive events.

Actually, it is possible for two types of outages simultaneously to affect one piece of equipment, such as the simultaneous occurrence of the disconnection of a network due to network protector failure and the disconnection of the same network unit due to a fault on the primary feeder to which it is attached. It is a moot point as to which type of difficulty is causing the outage. In practice, it does not matter because the outage would rarely, if ever, be recorded as caused by both types of difficulty. Therefore, since the recorded data from which the individual rates are determined do not or cannot account for this possible simultaneous creation of a single outage, they will probably be treated as mutually exclusive events.

The complete equation for the combination factor is

$$N^{C}a = \frac{\text{factorial } N}{\text{factorial } a \ X \ \text{factorial } (N-a)}$$

N = total number of units involved

a = number of units under consideration (i.e., either being in service or out of service)

The six combinations are:

1. P_1P_1
2. P_2P_2
3. P_3P_3
4. P_1P_2
5. P_1P_3
6. P_2P_3

Discussion

G. H. Arapakis (Consolidated Edison Company of New York, Inc., New York, N. Y.): In the Appendix the authors refer to an earlier paper presented at the American Power Conference in 1953, in which the values of P_1, P_2 and P_3 were treated as independent events, while in their present paper they are treated as mutually exclusive events. As I see it, when they are treated as independent events the combinational probability will include a factor q, or q to some power, q being the probability that the other event or events will not happen. Since this factor q or some power of q will not in general differ greatly from unity, the numerical results obtained for the combinational probabilities will not be very different whether P_1, P_2, and P_3 are treated as independent events or as mutually exclusive events. Am I correct in this comparison? I feel that it is important since apparently there is some question as to which assumption is correct.

In their earlier paper the authors devoted considerable attention to the case of two units out of service, a valuable point since for the most part it constitutes the basis for system design. The treatment of the three probabilities P_1, P_2, and P_3 as independent events permitted a relatively simple breakdown of the double contingency into the following five possible events: 1. two network units out on failure to close but no feeder outages, 2. one network unit out on failure to close and one feeder in the same vault taken out for work, 3. one network unit out on failure to close and one feeder in the same vault going out on fault, 4. one feeder out for work and a second feeder in the same vault going out on fault, and 5. two feeders in the same vault going out on fault. The breakdown of the double contingency into these five components is very valuable since it permits us to make a comparison of their relative importance as a guide for improvement in system design and operation that will reduce the probable frequency of the double contingency.

In the paper, treating P_1, P_2, and P_3 as mutually exclusive, they are lumped together to calculate first total probabilities and then an attempt is made at separation by a regrouping of terms. The mathematical justification for this regrouping and shifting of terms from one total probability to another is not very obvious and seems rather complicated, especially if it is necessary to apply it to vault installations with more than four units. The treatment of P_1, P_2, and P_3 as independent events, which the authors followed in their earlier paper, seems to avoid these difficulties, and since there is some doubt as to which assumption is correct, I would prefer to treat P_1, P_2 and P_3 as independent events.

The calculation of the combinational probabilities of the various events enumerated in the paper is, of course, no better than the operating statistical data for outages of cables and equipment, from which one must calculate P_1, which is the average probability that a network protector fails to close, P_2 the average probability that a feeder will go out of service on fault, and P_3 the average percentage of time that a feeder is out for work or maintenance. These will vary widely for different power systems, and even for different network areas in the same system. The factors which are responsible for these variations are the type and age of cables, the length of feeders, the type and age of network equipment, and the general operating conditions which make it necessary to take a feeder out for construction or maintenance work, more frequently and for longer periods in one system or area than in another. In calculations which we have made for the Consolidated Edison System, we have found it advisable at times to use different values of P_2 and P_3 in an attempt to take into account some of these differences in design and operation.

With respect to P_1, the average probability that a network protector fails to close, the authors have used data published by Edison Electric Institute for 1944 to 1946 on a-c network operation. From these data they have calculated that 2.92% of the network protectors fail to close. The correct statistic needed for the probability calculations is the percentage of protectors that would be found open when they should be closed, assuming that one would walk in on all the protectors at the same time. The data obtained over a period of time should, of course, be corrected for the number of units inspected, and if possible allowance should be made for the fact that inspections are not made at a uniform rate but may be lumped during certain times of the year as determined by weather and other system work. Also, it should be recognized that network protectors of certain periods have shown considerably higher rates of failures, and it may be necessary to take this into account for some of the network areas affected.

I should like also to comment briefly on the value of P_2, which is used in this paper to represent the average statistical probability that a feeder will be out of service on fault. For any one feeder the length of exposure is an important variable, but the wide variety of operating conditions inherent in an actual system will cause changes in the value of P_2. If it is true then that P_2 is subject to substantial variations from its average value, the occurrence of contingencies of higher order may not be as unlikely as probability calculations based on a constant value of P_2 would indicate.

N. M. Neagle and D. R. Nelson: Whether the individual types of outage should be treated as independent or mutually exclusive events will depend upon the definition and means of recording these events. They may be treated either way depending upon the data available. Because, after considerable discussion of the matter, it was felt that most utilities would probably define and record their occurrence as mutually exclusive events, they are treated as such in this paper.

If we define a feeder outage due to feeder maintenance as the removal of a feeder from service for planned or anticipated maintenance, and a feeder outage due to fault as a completely unanticipated or unplanned occurrence, it is apparent that the two events cannot occur simultaneously. Therefore, they are mutually exclusive events. The outage of a network transformer due to network protector failure is not a clear-cut independent or mutually exclusive event. If a network protector failure exists in a vault, thereby excluding its transformer from service, and a subsequent feeder outage removes the feeder from service, it is apparent that the occurrence of one event in no way affects that of the other. Therefore, the events are independent and not mutually exclusive.

If the network protector failure is known to have occurred before the feeder outage, the outage which it creates will probably never be distinguishable as an independent event. The matter of recording an outage will probably be that it was caused by one or another type of difficulty, but rarely, if ever, as caused by two types of difficulties. Thus, unless a particular effort is made to evaluate outage causes involving network protector failures as independent events, the matter of detection and recording will invariable be that of mutually exclusive events. Therefore, all three types of outages have been treated as mutually exclusive events in the paper. The accuracy of any calculations is naturally dependent upon the accuracy of the data available. This not only refers to numerical accuracy with regard to the particular situation in question or particular types of apparatus and conditions in question, but also to the proper allocation of the outage causes as independent or mutually inclusive events. If accurate data are not available and no distinction is made in recording the detection of outages between mutually exclusive and independent events, the over-all accuracy of the calculations will probably be just as good, if the outages are treated as independent events, as it might be if they were treated as mutually exclusive events.

There are a great many factors which can be taken into account to make the data and calculations more accurate. Unfortunately, the inclusion of these factors also makes the calculations more complicated. For a true picture of the condition, where accurate data are available, it may be placed in the equations defined, or a modification thereof, depending upon the conditions to be met.

Balancing Double-Wye High-Voltage Capacitor Banks

O. R. COMPTON
ASSOCIATE MEMBER AIEE

OCCASIONALLY double-wye-connected high-voltage capacitor banks using neutral-current relaying have sufficient residual current flowing in the neutral to cause improper relay operation, thus endangering the capacitors. This paper summarizes the problem, establishes limits for the maximum allowable residual neutral current, and presents methods for balancing the capacitor bank, if necessary, to reduce the residual neutral current to the allowable limit.

When a large, high-voltage capacitor bank is composed of multiple series sections per phase and a sufficient number of parallel capacitor units per series section to meet the minimum bank size requirement, at least one capacitor unit may be removed from any series section without encountering voltages in excess of 110 per cent (%) of rated voltage on the remaining capacitors.[1] However, the loss of two or more units in any one series section can produce dangerous overvoltages within the section in which the units are lost.[1,2]

Protective relaying is often used to give indication and/or trip the bank when a sufficient number of units are lost within one series section to cause the voltage appearing across that series section to exceed 110% of rated voltage.[1] Since the majority of power capacitors used in the United States in high-voltage banks are manufactured with a 0 to + 15% tolerance, there may be sufficient inherent unbalance to cause the protective relay scheme to operate prematurely or not to operate at all when needed, depending on the magnitude and phase angle of the residual current.[3]

In addition to unbalance caused by the variation in capacitance of individual units because of the 0 to 15% manufacturing tolerance, unbalance may also arise because of:

1. Units in upper tiers operating in higher ambients owing to warm air rising from lower tiers.
2. Capacitors in top tier being subject to direct sunlight will operate at higher internal temperatures than units in lower tiers.
3. Units in top tier casting their shadows on lower tiers, thus causing units in lower tiers to operate at a relatively lower internal temperature.

Specifically this paper deals with double-wye-connected banks using neutral-current relaying since it is the most widely used system. Its popularity is the result of its low cost when compared to other schemes which are also insensitive to external system conditions and yet extremely sensitive to unbalanced bank conditions. This was also the type of relaying used on the Virginia Electric and Power Company's banks which were balanced by the method presented in this paper.

It is our purpose to present a basis for theoretically establishing a satisfactory maximum allowable neutral residual current and two methods of balancing double-wye-connected capacitor banks when it is found that the initial residual neutral current exceeds the maximum allowable limit.

Nomenclature

Z_L = impedance of phase section in which one or more units in one series section has been lost
Z_n = impedance of normal phase sections
M = number parallel units per series section
N = number of series sections per phase section
K = number of units lost in one series section
K_1 = per cent of units lost in one series section
I_a = total bank current to phase in which K units have been lost
I_{a1} = normal total bank current

Paper 55-146, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 26, 1954; made available for printing December 8, 1954.

O. R. COMPTON is with the Virginia Electric and Power Company, Richmond, Va.

The author expresses his appreciation to P. B. Hendrickson for his assistance in the preparation of this paper. He also wishes to express his appreciation to J. A. Rawls, T. S. Martin, B. B. Brown, and B. F. Eldred, all of Virginia Electric and Power Company, for their encouragement and constructive criticism of this paper.

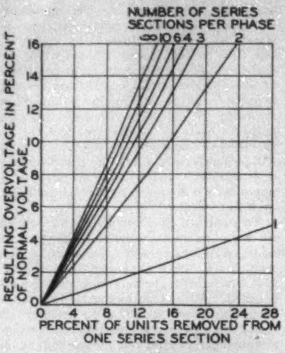

Fig. 1. Curve of overvoltage on remaining units in two series section versus percentage of units removed from that section

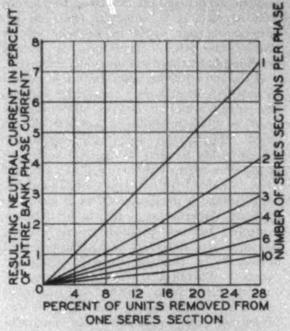

Fig. 2. Curve of neutral current versus percentage of units removed from one series section

I_L = current in phase section in which K units have been lost

I_{n1}, I_{n2}, I_{n3}, I_{n4}, I_{n5} = current in remaining phase sections

E = source line-to-neutral voltages

E_{ab}, E_{bc}, E_{ca} = source phase-to-phase voltage

e_f = voltage across series with K units lost

e_{n1} = voltage across series section under normal conditions

I_N = neutral current

$\%I_N$ = neutral current in % of normal total bank current

I_{aT} = assumed neutral current resulting from one unit being removed from top section of A phase

I_{aTa} = actual neutral current when one unit is removed from top section of A phase

I_N = actual residual neutral current with all units in service

Determination of Maximum Allowable Residual Neutral Current

Normally the neutral relay is set to pick up midway between the values of neutral currents theoretically obtained when the maximum permissible number of units and the maximum permissible number plus one unit in the same series section are lost. The maximum permissible number of units lost is defined as the maximum number that can be lost in one series section without the voltage across that section exceeding 110% of rated capacitor voltage.[1] This midway relay setting gives equal margin on either side to prevent premature relay operation when no more than the maximum permissible number are lost and to assure operation when one additional unit in the same series section is lost.

The maximum permissible number of units that may be removed from one series section may be determined by the curves in Fig. 1. The resulting neutral current may be determined for the loss of any number of parallel units in one series section by the curves in Fig. 2. The derivation of equations for Figs. 1 and 2 is shown in Appendixes I and II respectively.

The curves of Fig. 2 may also be used to establish the approximate neutral relay settings. For example, assume a double-wye-connected bank made up of three series sections per phase and eight parallel units per section. From Fig. 1 it can be determined that the maximum permissible units that may be lost is one. When two units in the same series section are lost, the bank should be relayed off. Therefore, the neutral-current relay should be set to pickup at a value of current equal to the loss of approximately one and one-half units or loss of (1.5/8)(100) = 18.75 units. Entering the curves on Fig. 2 at the loss of 18.75% units will indicate a relay setting of 1.8% of total bank current.

The relay setting in % of total bank current may be specifically determined by

$$I_R = {}^1/_2 \frac{150}{6N\left(\frac{M}{K+1}-1\right)+5} + \frac{150}{6N\left(\frac{M}{K}-1\right)+5} \qquad (1)$$

Maximum Allowable Normal Residual Neutral Current With All Units in Service

It can be readily seen that under normal conditions the maximum neutral residual current must be something less than one-half of the difference between the theoretical neutral currents obtained when the maximum permissible number of units and the maximum permissible number plus one unit are lost.

A realistic limitation of the maximum would be one-fourth of the difference in neutral currents when the maximum permissible number of units and the maximum permissible number plus one unit are lost. The maximum allowable residual current in % of total bank current may be determined by

$$I_R = {}^1/_4 \frac{150}{6N\left(\frac{M}{K+1}-1\right)+5} - \frac{150}{6N\left(\frac{M}{K}-1\right)+5} \qquad (2)$$

This value of maximum allowable residual current would provide ample margin against false tripping and at the same time avoid the trying task of obtaining a superfine degree of balance. The residual neutral-current component because of the difference in capacitance of units allowed by the 0 to +15% manufacturing tolerance will remain essentially constant for given bank. However, the residual neutral current may vary to a slight degree because of the difference in internal operating temperatures caused by the effect of upper tiers operating in higher ambients and being subjected to direct sunlight.

Variations in capacitance caused by different internal operating temperature could be substantial since the capacitance of an askarel-treated capacitor decreases approximately 1% for every 15- to 20-degree-centigrade rise in internal operating temperature. Experience has shown that units in the top tier can easily operate with internal temperature of 5 to 10 degrees centigrade above the internal temperature of units in the bottom tier.

Fortunately most high-voltage capacitor banks are so arranged that the effect of different internal operating temperatures is distributed throughout the bank

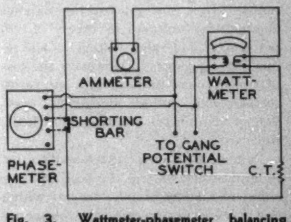

Fig. 3. Wattmeter-phasemeter balancing circuit

so that the approximate respective balance is maintained. However, there is ample margin to allow for some degree of changing unbalance caused by different internal operating temperature when the value of maximum allowable residual current specified in the foregoing is maintained.

Fig. 5. No. 5 capacitor bank, Peninsula Substation

Field Balancing of Double-Wye-Connected High-Voltage Banks

The following discussion describes the general procedure incorporated to balance the no. 4 and no. 5 double-wye-connected 24,750-kilovar 108-kv 3-phase capacitor banks at the Virginia Electric and Power Company's Peninsula Substation. Both banks are identical in design and are shown schematically in Fig. 4. Bank no. 5 is shown in Fig. 5. Each bank is made up of standard 25-kilovar 4,160-volt single-phase distribution capacitors with 15 series sections per phase and 11 parallel units per series section.

The resulting voltage rise across a series section caused by the loss of one capacitor within that section is 9%, as determined from Fig. 1. Since the loss of two units in the same series section results in a voltage exceeding 110% of rated capacitor voltage, it is necessary to relay the bank off when more than one unit is lost in the same series section.

The theoretical neutral-current flowing when one and two units are lost is 0.24 and 0.51 ampere (amp) respectively. Therefore, the neutral relay is set to pick up at (1/2) (0.24+0.51) or 0.375 amp. Likewise, the maximum allowable residual neutral-current limit is established to be (1/4) (0.51–0.24) or approximately 0.07 amp. Assuming that the maximum allowable residual neutral-current limit is established at 0.07 amp, the resulting neutral currents would range between 0.24±0.07 and 0.51±0.07 amps if one and two units were lost respectively. The exact value of the resulting neutral currents when one or two units are lost depends on the particular phase group in which the units were lost and the magnitude and phase angle of the residual neutral current.

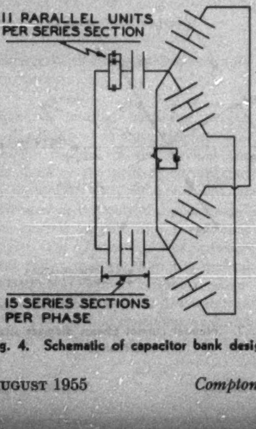

Fig. 4. Schematic of capacitor bank design

Each bank was energized to determine the initial residual neutral current. It was found that the initial residual currents were 0.295 amps for bank no. 4 and 0.265 amps for bank no. 5. It is obvious that these magnitudes of residual neutral current would cause false relay operation. For example, in bank no. 4, the loss of one unit in any one of the six phase groups could cause a resulting neutral current of 0.24±0.295 amp. With the relay set at 0.37 amp, the bank could be easily relayed off unnecessarily. Similarly, with two units lost, the neutral current in bank no. 4 could range between 0.51±0.295 amp, and this could result in two units being removed without encountering sufficient neutral current to pick up the relay and thus endangering the remaining units in the series section containing the lost units because of overvoltage operation.

The following steps constitute the general procedure followed in balancing the no. 4 and no. 5 banks at the Peninsula Substation:

1. Determine the magnitude of initial residual neutral current.
2. Determine phase angle of initial residual neutral current.
3. Determine the phase sections contributing to the initial residual neutral-current and capacitance change necessary to reduce the residual neutral current to within the maximum allowable limits.
4. Interchange high and low capacitance units to accomplish the capacitance change dictated by step 3.

Magnitude of Initial Residual Current

The magnitudes of the initial residual currents were determined by energizing each bank and measuring the neutral current on the secondary side of the 1-to-1 neutral current transformer. The initial residual neutral currents were 0.295 and 0.265 amp respectively for banks no. 4 and no. 5.

Thase Angle of Initial Residual Current

Neutral-current measurements were made on each bank with one capacitor out of one section of one phase group. This test was repeated six times to enable the phase angle of the initial residual neutral current to be determined by graphical analysis. It would, of course, have been possible to determine the phase angle with fewer measurements. For each test the bank was normal except one capacitor was removed from the series section nearest the neutral in a different phase group each time. The results of these tests are shown in Table I for bank no. 4.

It was calculated that the phase group in which the one unit was removed would supply a 0.24-amp neutral current in phase with the line current. Therefore, six vectors, each 60 electrical degrees apart and each with a magnitude of 0.24

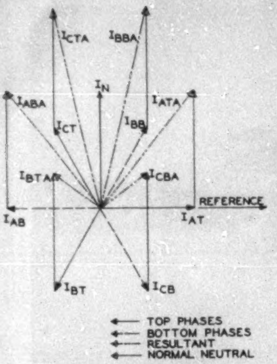

Fig. 6. Neutral current phasor diagram before interchange

amp were plotted, as shown in Fig. 6. The magnitude only was measured for each of the six conditions where one unit was removed, as described in the foregoing. This magnitude was the vectorial sum of the 0.24-amp in-phase component plus the component produced by the capacitance unbalance (initial residual current) at an unknown angle.

If a circle is drawn with a radius equal to the initial residual current, as found in the foregoing, and centered at the head of a 0.24-amp in-phase phasor, that circle will be the locus of all possible total neutral currents when one unit is removed from that phase group. A second circle with a radius equal to the total neutral current with its center at the origin is drawn which will also be the locus of all possible total neutral currents. These two circles intersect at two points; one of which is the locus of the initial neutral-current phasor.

For example, in Fig. 6, a circle with radius equal to *I* normal is drawn with the head of phasor I_{AT} as the center. Then a second circle is drawn with the center at the origin and a radius equal to the total neutral current measured when one unit is removed from the *A* phase, top group. These two circles intersect at the head of phasor I_{ATA} and, at a second point, 180 electrical degrees (through the head of phasor I_{AT}) from I_{ATA}. A line drawn from the head of phasor I_{AT} to each of these intersecting points will be the two possible normal unbalance-current phasors. These phasors are equal in magnitude and are 180 electrical degrees apart in angle. This procedure is repeated for another phase group and it becomes apparent which is the correct direction for the normal unbalance-current phasor.

Table I. Neutral Currents Prior to First Interchange, Bank No. 4

Location of Unit Removed	Neutral Current, Amp
A—top phase	0.355
B—top phase	0.110
C—top phase	0.530
A—bottom phase	0.355
B—bottom phase	0.560
C—bottom phase	0.215

The graphical analysis for determining the phase-angle relationship of the initial residual or normal unbalance current is shown in Fig. 6 for bank no. 4. This current was found to be $0.295\underline{/270^\circ}$ amp. An analysis of Table I will reveal that the loss of one unit from any section in *B*-bottom phase or *C*-top phase, of bank no. 4 would have produced a circuit-breaker trip with a relay setting of 0.37 amp. In the remaining phase groups, two or more capacitors would have to be removed from the same series section to produce a circuit-breaker trip.

Phase Groups Contributing to Unbalance

A study of the phasor diagram for bank no. 4 shows that the neutral current was high on *B*-bottom phase and *C*-top phase when one capacitor was removed from these respective groups. The neutral current was equal in both *A*-top and *A*-bottom phase groups when one capacitor was removed from either of these groups.

It was assumed that *B*-bottom phase and *C*-top phase contributed equally to the initial neutral current, i.e., 0.295/2 or 0.148 amp was contributed by each of these phase groups. The phase angle between *B*-bottom phase and *C*-top phase is about 30 degrees above and below the initial residual neutral current. Therefore, the gross current component contributed by *B*-bottom phase and *C*-top phase equals (0.148/cos 30°) or 0.171 amp.

If 0.24 amp equals the theoretical neutral current produced by the loss of one unit, the 0.171-amp component equals the current produced by the equivalent loss of 0.171/0.24 or 0.71 of a unit. This indicates that a balance could be obtained by moving 0.71/2 or 0.35 of a unit from *B*-top phase to *B*-bottom phase and 0.35 of a unit from *C*-bottom phase to *C*-top phase.

Table II. Neutral Currents After First Interchange, Bank No. 4

Location of Unit Removed	Neutral Current, Amp
A—top phase	0.330
B—top phase	0.110
C—top phase	0.328
A—bottom phase	0.201
B—bottom phase	0.375
C—bottom phase	0.022

Calculation of Number of Units to Interchange

Each unit contains approximately 4.0 microfarads (mf) of capacitance; therefore, it was necessary to interchange (0.35) (4) or 1.40 mf between the *B*-phase and *C*-phase groups. To determine which units to interchange, a capacitance bridge was used to measure the capacitance of units in the top and bottom tiers of phases *B* and *C*. Individual unit capacitance was taken of each individual unit, starting with the series sections nearest the neutral. This procedure was continued until a sufficient number of high and low units were found to make a total transfer of 1.24 mf from *B*-top phase to *B*-bottom phase and from *C*-bottom to *C*-top phase respectively. To accomplish this change in capacitance, 20 units were interchanged in the *B*-phase and 18 units in the *C* phase. After the interchange was completed, a check was made of the residual neutral current and it was found to be 0.13 amp. Therefore, it was necessary to repeat the balancing procedure.

The results of tests taken to determine the phase angle of the residual current after the first interchange are shown in Table II. Fig. 7 shows the graphical analysis for determining the new residual neutral current to be $0.13\underline{/182^\circ}$ degrees amp.

An analysis of Fig. 7 indicated that an additional transfer of 0.84 mf was needed from *B*-top phase to *B*-bottom phase.

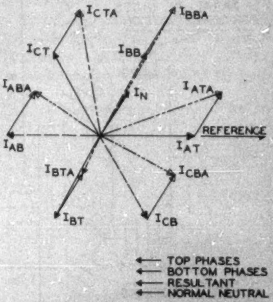

Fig. 7. Neutral current phasor diagram after first interchange

The 0.84-mf change was accomplished by interchanging 12 additional units in the *B* phase. The residual neutral current was checked after the second interchange and was found to be 0.046 amp which is within the maximum allowable residual neutral current of 0.07 amp.

The same procedure was used to balance bank no. 5. The initial neutral residual current was 0.265 amp. After interchanging 26 units in *B* phase and 18 units in *C* phase the residual neutral current was reduced to 0.098 amp. A second interchange of 12 units was made in *C* phase which reduced the residual neutral current to 0.072 amp, which is considered satisfactory.

SUBSTATION OPERATING PROCEDURE

It was first decided to lower the system voltage at the Peninsula Substation each time the banks were energized for a neutral-current measurement test to offset the voltage rise caused by the capacitors. This required considerable time for system co-ordination before each test and, as a result, tests proceeded rather slowly the first day. Since it required only approximately 3 seconds to make each current measurement, it was decided by the system operator that no voltage drop would be required before energizing the bank. The voltage reduction is more harmful than the 3-second voltage rise. After this change in procedure was made, neutral-current measurement tests were conducted very rapidly.

When making capacitance measurements prior to selecting specific units to interchange, it was found that approximately four units had to be measured for capacitance for every two units interchanged. In bank no. 4, 100 units were measured before selecting 50 to interchange; 112 units were measured in bank no. 5 before selecting 56 units to interchange. It required 4 days to attain the proper balance on both banks.

Balancing With Phasemeter and Wattmeter

Since the original balancing of the capacitor banks at Peninsula Substation, a simpler method of determining the phase angle of the neutral current has been developed. Either a phasemeter can be used to compare the phase angle of the neutral current with a reference potential, or a wattmeter for comparison of real power derived from the neutral current with each of six reference potentials. A circuit is used as illustrated in Fig. 3. The residual neutral current and one of six potentials are utilized as input quantities into a phasemeter and a wattmeter; see Fig. 3. The six potentials are 60 electrical degrees apart. With these quantities, it is possible to determine the phase angle of the residual neutral current and then proceed with the balancing, as discussed in the foregoing.

The wattmeter may have an application in normal operation. It is the practice of the operating department to inspect the capacitor installation once a week. This inspection is for blown fuses and other discrepancies. Since there are almost 4,000 capacitor-unit fuses in the installation, the inspection is quite time-consuming. A single-phase wattmeter might be installed on the control panel for each bank. A blown fuse would cause a rise in the residual neutral current of the bank which would be indicated on an ammeter on the control panel. If the inspector notes a rise in the residual neutral current, he would proceed to apply the different potentials to the wattmeter with a rotary switch. By noting the maximum wattmeter indication, he could determine which phase group has a blown fuse. The equipment for this installation would not be expensive.

Conclusions

The following conclusions are based on the characteristics and procedure for balancing high-voltage double-wye-connected capacitor banks:

1. Double-wye-connected high-voltage banks may have sufficient initial residual current to cause improper operation of the neutral-current relay used to prevent overvoltage operation of capacitor units when an excessive number of units are lost in one series section.

2. The normal residual neutral current with all units in service is the result of:

   a. A 0 to +15% manufacturing tolerance of individual capacitor units.

   b. The variation in the capacitance of units due to different unit temperatures resulting from capacitors in the top tiers operating at higher ambient temperatures than those in the lower tiers. This is because warm air rises from below; the top tiers get direct sunlight, and they cast their shadows on the lower tiers.

3. It may be found necessary to balance the bank by shifting individual capacitor units to reduce the residual neutral current to within an allowable limit to permit proper neutral-relay operation. The maximum allowable residual current is specified as one-fourth of the difference between the neutral currents obtained when the maximum permissible number of units is lost and the permissible number plus one additional unit.

4. Shifting units will counteract unbalance caused by 0 to +15% manufacturing tolerance. Unbalance caused by item *b* in conclusion 2 usually may be neglected providing the bank is arranged so that changes in capacitance caused by different internal operating temperatures will be equally distributed throughout all six phase groups.

5. Double-wye-connected capacitor banks may be easily balanced in the field by using the following procedure, when it is found that the initial residual neutral current exceeds the maximum allowable value specified in conclusion 3:

   a. Determine magnitude and phase angle of initial residual current.

   b. Determine phase groups contributing to unbalance and calculate magnitude of capacitance change in the various phase groups necessary to reduce the initial residual current to near zero.

   c. Balance bank by interchanging high- and low-capacitance units to achieve calculated capacitance change necessary to attain proper balance.

6. Balancing in the field can be eliminated if proper consideration is given to the problem by the engineers designing the bank. If the phase groups are balanced on paper and a strict unit placement program is adhered to during field erection, there should be no problem of tolerance unbalance.

7. A single-phase wattmeter or a phasemeter can be used to determine which phase group contains a blown fuse on a large bank.

Appendix I. Determination of Neutral Current

The following equations can be written by inspection of Fig. 8

$$I_{n1}+I_{n2}+I_{n3}-I_N=0 \quad (3)$$

$$I_L+I_{n4}+I_{n5}+I_N=0 \quad (4)$$

$$I_{n2}=I_{n3}=I_{n4}=I_{n5} \quad (5)$$

Solving equations 3, 4, and 5 for I_N

$$I_N=\frac{I_{n1}-I_L}{2} \quad (6)$$

Neutral current in % at normal total bank current is

$$\%I_N=\left|\frac{I_N}{I_{a1}}\right| 100 \quad (7)$$

Normal total bank current when $Z_L=Z_n$ is

$$I_{a1}=\frac{2E}{Z_n} \quad (8)$$

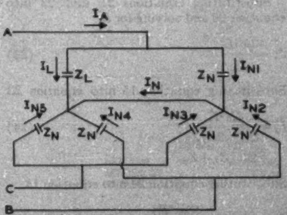

Fig. 8. Currents in double-wye-connected capacitor bank

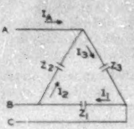

Fig. 9. Currents in equivalent delta-connected capacitor bank

Substituting equation 8 into equation 7

$$\%I_N=\frac{Z_nI_N\ 100}{2E} \qquad (9)$$

By inspection of Fig. 8

$$I_a=I_{n1}+I_L \qquad (10)$$

$$I_L=I_a\frac{Z_n}{Z_L+Z_n} \qquad (11)$$

$$I_{n1}=I_a\frac{Z_L}{Z_L+Z_n} \qquad (12)$$

Substituting equations 11 and 12 into equation 6

$$I_N=I_a\frac{(Z_L-Z_n)}{(Z_L+Z_n)} \qquad (13)$$

To solve for I_a convert double-wye network (Fig. 8) to delta network (Fig. 9)

$$Z_1=Z_n+\frac{Z_n(Z_L+Z_n)}{4Z_L} \qquad (14)$$

$$Z_2=\frac{Z_n}{2}+\frac{2Z_LZ_n}{Z_L+Z_n} \qquad (15)$$

$$Z_3=\frac{Z_n}{2}+\frac{2Z_LZ_n}{Z_L+Z_n} \qquad (16)$$

By inspection of Fig. 9

$$I_a=I_3-I_2 \qquad (17)$$

$$I_a=\frac{E_{ab}}{Z_2}-\frac{E_{ca}}{Z_3} \qquad (18)$$

From equations 15 and 16

$$Z_2=Z_3 \qquad (19)$$

Substitution equation 19 into equation 18

$$I_a=\frac{1}{Z_2}(E_{ab}-E_{ca}) \qquad (20)$$

The following voltage equalities may be written

$$E_{ab}=\sqrt{3E} \qquad (21)$$

$$E_{ca}=a\sqrt{3E} \qquad (22)$$

Substituting equations 21 and 22 into equation 20 and solving for I_a

$$I_a=\frac{3ja^2E}{Z_2} \qquad (23)$$

Substituting equation 15 into equation 23

$$I_a=\frac{3ja^2E}{\frac{Z_n}{2}+\frac{2Z_LZ_n}{Z_L+Z_n}} \qquad (24)$$

Substituting equation 24 into equation 13

$$I_N=\frac{(3ja^2E)}{(Z_LZ_n+Z_n^2+4Z_LZ_n)}(Z_L-Z_n) \qquad (25)$$

Substituting equation 25 into equation 9 and neglecting voltage and impedance angles

$$\%I_N=\frac{3}{2}\frac{(Z_L-Z_n)}{(5Z_L+Z_n)}\ 100 \qquad (26)$$

However

$$Z_n=\frac{-jXcN}{M} \qquad (27)$$

$$Z_e=\frac{-jXc(N-1)}{M}+\frac{-jXc}{M-K} \qquad (28)$$

Substituting equation, 27 and 28 into equation 22

$$\%I_N=\frac{150}{6_N\left(\frac{M}{K}-1\right)+5} \qquad (29)$$

Equation 27 in terms of % units lost is

$$\%I_N=\frac{150}{6_N\left(\frac{100}{K_1}-1\right)+5} \qquad (30)$$

Appendix II. Determination of Resulting Overvoltage

$$e_f=\frac{I_e(-jXc)}{M-K} \qquad (31)$$

$$e_{n1}=\frac{I_{a1}(-jXc)}{2M} \qquad (32)$$

$$\%e_f=\frac{e_f}{e_{n1}}\ 100 \qquad (33)$$

Substituting equations 31 and 32 into equation 33

$$\%e_f=\frac{I_e}{I_{a1}}\frac{(2M)}{(M-K)}\ 100 \qquad (34)$$

Substituting equations 8 and 25 into equation 34 and neglecting voltage and impedance angles

$$\%e_f=\frac{6MZ_n}{(5Z_1+Z_n)(M-K)}\ 100 \qquad (35)$$

Substituting equations 27 and 28 into equation 35

$$\%e_f=\frac{600MN}{6N(M-K)+5K} \qquad (36)$$

Equation 36 in terms of % units lost is

$$\%e_f=\frac{60{,}000N}{6N(100-K_1)}+5K_1 \qquad (37)$$

Discussion

E. C. Starr (Bonneville Power Administration, Portland, Oreg.): We have found Mr. Compton's excellent analysis of double-wye capacitor-bank currents very interesting since it extends certain considerations which led us to a somewhat different form of 115-kv bank arrangement in 1949. At that time we were considering two banks of capacitors with roughly the same rating as those described in the paper. One fact that immediately impressed us was that a sensitivity problem was apparent in any relaying scheme intended to back up the individual fuses. Whether relaying was attempted by current or voltage to ground or between floating neutrals, the % overvoltage developed corresponded roughly to the % of units removed from one layer, and the relaying quantity was disturbingly small. This promised to be further aggravated by the natural fundamental unbalance between legs and by harmonics, and inrush and external fault currents in the case of a grounded neutral.

In view of the great sensitivity required of any relay under these conditions, we were reluctant to place any more reliance for protection than necessary on relaying. A small change in calibration could permit sustained overvoltages. It seemed to us that the best possibility of avoiding overvoltage was to keep as many capacitor units as possible in parallel per layer to avoid the coincidence of failures which might lead to overvoltage. Our failure rate on capacitors which have been in service for some time is less than 0.1% per year. On this basis, and with inspection intervals of 1 week or less, the probability of overvoltage is very low.

We have adopted the grounded-neutral single-wye form of arrangement, having 25-kilovar 7,960-volt capacitors protected by individual indicating fuses. The grounded wye has the advantages of station surge protection and reduced recovery voltage during switching, and the disadvantage of complicating the relaying by inrush and harmonics. The inrush we found high enough to damage neutral-current transformers, but standard heavy-duty carbon telephone blocks on the primaries have been effective in eliminating that problem. Third-harmonic by-pass filters have been designed which are effective with one form of overcurrent relay.

A bank may have eight or nine series groups of from 20 to 30 capacitors in parallel per phase. The expectancy of three fuses blowing during 1 week in one layer of 20 in any bank is less than once in a 1,000,000 years. On this basis, we are inclined to question the need for neutral relays, although we still employ them.

N. Rex Sheppard (General Electric Company, Hudson Falls, N. Y.): Mr. Compton's paper is very well written and explains a very unique and worth-while method of balancing double-wye high-voltage capacitor banks. These comments are, therefore, not intended to discredit his very fine work. It does appear, however, that since more and more high-voltage capacitor banks are being applied, careful consideration should be given as to a preferred method of designing them.

Much experience has been gained by utilities and manufacturers since high-voltage banks were first used to any great extent a few years back. Much of this experience has been acquired since the bank referred to by the author was first designed and built. In view of this experience, it seems worth while to pose two questions:

1. Is relay protection to prevent overvoltage across individual capacitor units as a result of losing units in any particular series section justifiable in view of the probability of damage and the expense and difficulty involved in attaining an effective relay system?

2. Is it wise to break an individually switched capacitor bank into two paralleled single-wye banks with line terminals connected to a single circuit breaker and neutrals interconnected? This connection is often referred to as a double-wye bank.

It may be worth while to clarify the nature of the relay protection we are discussing. It should not be confused with the use of normal overload relays to protect the bank and system against the effects of bus faults occurring between the capacitor units and the circuit breaker. Nor should it be confused with the protection against case-bursting and service interruption afforded by individual capacitor unit fuses.

This particular type of relaying is usually thought of as providing protection against the contingencies of:

A. Overvoltage on individual capacitor units as a result of losing a given percentage of units from any one single series section. This may result since, as units fail and are removed from any one series section, the impedance of that section increases. However, since there are many sections in series, the effect of the increased impedance in one section does not decrease the phase current in the same proportion. The result of the slightly reduced current flowing through a more markedly increased impedance causes a resulting higher voltage to be impressed across the remaining units in that section. This condition is difficult to detect and protect against. It is, however, an improbable occurrence if the bank is periodically inspected. There are considerations in design which can further reduce the already small probability of incurring damage in this way.

B. An arc over across a series section as the result of a foreign object initiating a short circuit. As with any high-voltage equipment with exposed buswork and terminals, it is possible for foreign objects to initiate an arc. The difference between this and most equipments is that the arc is not line to ground or line to line, but is across only a portion of the line-to-neutral voltage. As a result, the phase current may not be increased sufficiently to cause normal overcurrent operation of the circuit breaker.

Based on observations and experiences shared with many high-voltage capacitor users throughout the country, we feel that contingency A can best be avoided by:

1. Designing the bank with as few series sections and as many parallel units in each section as possible. This can be done by:

a. Making each individually switched bank as large as possible based on the allowable voltage step. This, of course, also reduces the investment in switchgear.

b. Adopting the single-wye bank in preference to the double-wye bank.

c. Using as high a capacitor unit voltage rating as is available as a standard that will divide evenly into the required phase voltage of the banks. The small present-day difference in cost between medium-voltage (2,400 to 4,160-volt) and high-voltage (4,800 to 7,960-volt) capacitor units make this suggestion economically sound.

2. Periodically inspect the individual capacitor fuses which serve to remove as well as indicate a failed unit. When a failed unit is detected, it should be replaced along with the fuse as soon as practical to do so. It is felt that effective relaying to protect against this contingency is difficult to accomplish and may not be economically justifiable.

Contingency B may be a worth-while consideration particularly on grounded-wye banks where it is relatively inexpensive to accomplish. On grounded-wye banks, the protection can be effected by a relay system requiring a medium-voltage current transformer, a current relay incorporating inverse time-delay characteristics and a third-harmonic filter, and spark-over gaps connected across the current transformer primary. The gaps are to protect the current transformer and secondary circuit from the high voltage which might otherwise appear across it when the bank is switched on and off the line. Such a circuit is indicated in Fig. 10. On ungrounded-wye banks, the protection is similar except a potential transformer and a voltage relay are used.

Although the current or the voltage, as the case may be, is affected by system balance and capacitor bank balance, the circuits are relatively free from misoperation when set to protect against contingency B. The reason for this is that the relay need not be set nearly as fine as if designed to detect contingency A.

Most systems proposed are based on detecting the voltage at and/or current flowing through the neutral connection. The conditions at the neutral are necessarily dependent upon the vector angle and magnitude relationship of the impedances in each phase or leg of the capacitor bank. The overvoltage condition is, however, largely the result of the change in impedance in a particular series section. Therefore, with all systems proposed, except more expensive methods which measure and compare the voltages appearing across each series section (quite expensive), the relays can operate in any of three different ways:

1. They may operate as desired to guard against a predetermined overvoltage appearing across a single series section. This operation would be assured if all successive unit failures occurred in the same series section. This is a very improbable occurrence.

2. They may operate to relay the bank off the line when it is not necessary to do so from an overvoltage consideration. This may be called false operation and is likely to occur much more frequently than operation (1). This may occur when:

a. Successive faults occur in the same phase leg, but in different series sections (more likely than in same section).

b. Successive faults occur in different phase sections such that the resultant vector effect on the neutral causes relay operation (also more likely than failures in same section which might cause overvoltage).

c. Change in balance of capacitor bank because of temperature variations between one part of the bank and another. (Referred to in paper).

d. In case of a single-wye bank, the relay (being set sensitively to detect operation 1) may operate on a slight unbalance in system voltage. This is a point in favor of the double-wye connection.

3. The relay system may not operate when an overvoltage is applied in a particular series section as the result of the balancing effect of other failures in other phase legs of the bank (or banks in the case of the double-wye system). This is, just as operation 1, an improbable occurrence as a result of the high reliability of modern power capacitors and the inspection practices of most operators. It does, however, indicate a considerable limitation on relay methods.

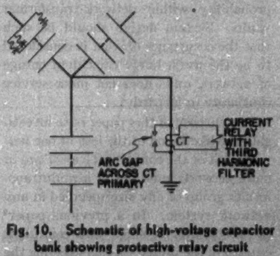
As pointed out previously, the single-wye bank has the disadvantage over the double-wye bank in that a sensitively set relay would be affected by system voltage unbalance. There are, however, certain advantages of the single-wye bank which may well overshadow this one disadvantage. These are:

1. Twice as many units are placed in parallel in each series section. This means that twice as many units must fail in a particular section of the single-wye bank to cause the same overvoltage which might result from a given number of failures in a section of the double-wye bank.

2. The initial cost of the single-wye bank is usually considerably less than that of the double-wye bank.

It is, therefore, a worth while consideration that the single-wye bank be used in preference to the double-wye bank and that the value of relay protection to guard against individual unit overvoltage be made on the basis of its need, cost, and reliability.

By taking advantage of the added benefits of the single-wye bank, by switching high-voltage banks in as large increments as practical from a voltage step consideration, by making use of as high-voltage standard capacitor units as possible in original design, and by initiating a periodic bank inspection procedure, it is my feeling that the



CT
CURRENT RELAY WITH THIRD HARMONIC FILTER
ARC GAP ACROSS CT PRIMARY

Fig. 10. Schematic of high-voltage capacitor bank showing protective relay circuit

user will attain the highest satisfaction from their high-voltage capacitor banks. Although I have strayed from the basic topic of this paper on balancing, I felt that the discussion would be of interest, since the fine balance is only required if relaying to protect contingency A is being considered.

O. R. Compton: Mr. Starr and Mr. Sheppard are both advocates of the single, grounded-wye-connected design for capacitor banks of large size, and I appreciate their comments very much. As Mr. Starr points out, the best form of overvoltage protection is obtained by using as many capacitors as possible in parallel and this is an inherent characteristic of the single-wye design.

It would be most helpful to the industry if a paper were prepared by Mr. Sheppard expanding the thesis he propounds in his discussion. Since the Virginia Electric and Power Company capacitor installation has been balanced by the methods described in my paper, we plan to continue operation as a double-wye bank. Future installations will be engineered in line with the latest practices of the industry.

One problem in the use of single, grounded-wye-connected capacitor banks is the possibility of telephone interference where telephone toll lines are in the vicinity. This problem will need additional exploration before the single-wye bank can come into general usage.

SINCE the advent about 30 years ago of the 120/208-volt secondary-network system of electric power distribution in commercial areas of cities, both load density and the prevalence of large, concentrated loads have continued to increase. This load growth has in turn brought about a growing tendency for added increments of network-system capability to assume the form of multiple-network-transformer installations. Moreover, the coming popularity of 265/460 volts as another secondary-network utilization voltage will accelerate future needs for multiple-transformer, spot-network installations.[1]

The allowable loading of a multiple-transformer network-unit installation may be based on the loss of one network unit or on the coincident loss of two network units. In the event of such contingencies involving the loss of network units in a particular vault or group of neighboring vaults, the network units remaining in service within that group must be capable of carrying the load. Network planning and design must therefore include evaluation of coincident-outage probability within network-transformer vaults. System design should be such that the occurrence of what it considered to be the worst likely coincident outage of network units does not place service continuity in jeopardy.

The purpose of this paper is to investigate the likelihood of the loss of one network unit or the concurrent loss of two or more network units out of a multitransformer group of any size specified in any network system. In a previous paper[2] the probability of single and coincident outages of the primary feeders serving the network units was discussed for network systems in general. This earlier analysis dealt with the factors which govern the adequacy of primary-feeder capability from the standpoint of primary-feeder outage likelihood. The present paper extends the probability analysis of network system capability into the network-unit vaults.

Causes and Effects of Network-Unit Outage

A modern secondary-network unit consists of a transformer which steps down the primary-feeder voltage to utilization voltage, and a network protector located in the low-voltage leads of the network transformer; see Fig. 1. The network protector is a special type of circuit breaker equipped with relaying which will trip the circuit breaker in the event of reverse power flow, or automatically close the breaker if the voltage across the open protector is such that power will flow from the primary feeder into the low-voltage network. The network protector also contains a set of fuses, one in each phase. Since the network-protector circuit breaker can trip only on reverse power, the fuses serve as a means for interrupting currents that are not interrupted by the network-protector circuit breaker or other means.

A primary-feeder fault results in the tripping, due to reverse-power flow, of the network protectors in all the units supplied by that feeder. Similarly, intentional de-energization of a primary feeder by tripping its circuit breaker at the source results in the opening of the network protector in every unit supplied by that feeder, due to reverse magnetizing current flow from the low-voltage system to the network transformers whose primary feeder is de-energized.

A network unit is unable to carry load if its primary feeder is de-energized, or if its network-protector circuit breaker is open. Network-unit outage will also result from blown network-protector fuses, but the effect of this cause of outage on the probability of network-unit outage is relatively small and will not be considered in this paper.

The probability of outage to a network unit is the sum of the probabilities of its primary feeder being out of service and its network protector being permanently open after having failed to close. Each of the other possible causes for network-unit outage, such as blown network-protector fuses, has a certain probability and they all can be lumped into a single value and added to the feeder-outage and protector failure-to-close probabilities to obtain the total probability of outage for that unit.

Secondary-network system designers and operators may prefer to deal with outage probabilities in terms of their likely frequency of occurrence expressed in units of years rather than with pure probability numbers which are often difficult to visualize in terms of the quantities that can be obtained from network operating experience. Hence, in the probability analyses of this paper certain approximations are introduced which permit coincident-outage frequency of network units in the same vault to be expressed in terms of such quantities as the number of network-feeder outages per year and the number of times per year that a network protector is found unable to close during a routine vault inspection.

A secondary-network system is gener-

Paper 55-161, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 26, 1954; made available for printing December 6, 1954.

DAVID N. REPS is with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

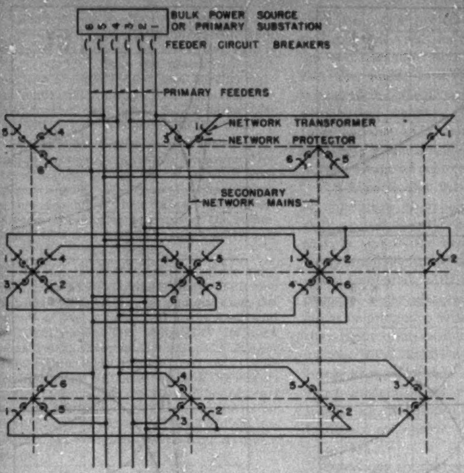

Fig. 1 (left). Part of a secondary-network system, showing six primary feeders interlaced among network vaults housing one, two, three, or four network units

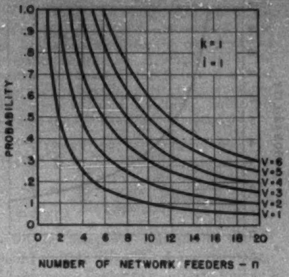
Fig. 2 (right). The probability that a single network feeder outage will affect one of the units in a particular v-unit vault



ally so designed that the loss of one primary-feeder circuit can be sustained indefinitely without excessively overloading the network units remaining in service. During such a feeder outage, single network units in certain vaults throughout the system are de-energized. In any one of these vaults, there is also some small probability that the network protector in one of the other network units will be open and unable to close. A network protector that has failed to close can in no way damage its network unit, which will be unable to carry load. However, the coincident loss of two, or more, network units in any one vault or neighboring group of load-sharing units may result in overloading the units remaining in service. The equations and computation methods presented in this paper make it possible to evaluate the risk of coincident outage of network units in vaults or groups of neighboring units.

Outages of Primary Feeders Serving a Vault

When one or more interlaced primary feeders are concurrently out of service, vaults located throughout the network area are affected. For example, during

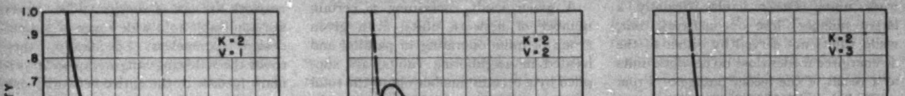


Fig. 3. The probability that the coincident outage of two network feeders (k=2) will result in the loss of one (i=1), or the coincident loss of two (i=2) network units in a particular v-unit vault

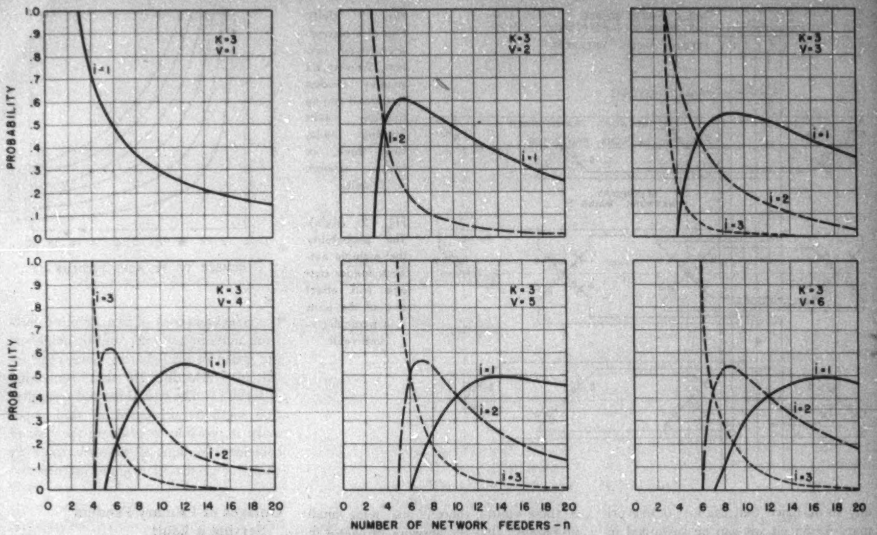

Fig. 4. The probability that the coincident outage of three network feeders (k = 3) will result in the loss of one (i = 1), two (i = 2), or three (i = 3) network units in a particular v-unit vault

the simultaneous outage of two feeders, some vaults may as a result lose two network units. Other vaults (usually a larger number) lose one network unit, while vaults not served by either of the de-energized feeders lose no network units as a result of the feeder outages. From methods described in the preceding paper[2] on primary-feeder coincident-outage likelihood, the frequency of occurrence of coincident feeder outages can be evaluated for any network system, in terms of one of more of the following factors, all of which influence or are influenced by secondary-network design:

1. Total number of primary feeders.
2. Total mileage of primary-feeder circuit.
3. The number of accidental feeder outages per year.
4. The number of accidental feeder outages per 100-mile-years of feeder circuit.
5. The total scheduled feeder-outage time per year.
6. The time duration of existing or future feeder outages.

All of these determinants of primary-feeder coincident-outage likelihood pertain to the network system as a whole. The results of an analysis based on such network-wide considerations can be extended to include coincident-outage likelihood of the network units in any given vault or within any given group of network units.

A given vault containing a certain number of network units, or a given group of units operating in parallel and located in neighboring vaults, are supplied by a certain number out of the total number of feeders to the network. In very large multiunit vaults, or in a group containing a relatively large number of network units, every one of the network feeders may be present. For instance, in a 4-feeder network, the four network units located in a particular vault would each be served by one of the total number of four network feeders. More often, however, even in multiunit vaults or groups, fewer than the total number of network feeders are represented. System-wide feeder-outage probabilities applicable to all the network feeders as a whole must be modified to apply to the fraction of the network feeders serving a particular vault or group of units.

The curves of Figs. 2, 3, and 4 are for the purpose of adjusting primary-feeder outage probabilities, computed for the entire system, for application to primary feeders serving an individual vault or group of network units. These curves can be used to find the probability for a feeder outage, or the coincident outage of two or more feeders to the same vault or group of network units when a specified number of feeders serving the entire network are out of service. The curves are applicable to a wide range of system design parameters. Specifically, they cover the following ranges: up to 20 primary feeders to the entire network; one to six network units within the same vault or group; the outage of one or the coincident outage of two or three network feeders; the loss of one or the coincident loss of two or three network units is the same vault or group as a result of network-feeder outages. The method used for deriving these curves is outlined in Appendix I. The following example will illustrate one use for the curves of Figs. 2, 3, and 4.

EXAMPLE: COINCIDENT FEEDER OUTAGES IN THE SAME VAULT

A network vault contains four units served by four different primary feeders out of a total of ten feeders to the entire network.

1. For what fraction of the total number of times during which two network feeders are simultaneously out of service will the two affected feeders be two of the four serving the vault?
2. For what fraction of the total number of 2-feeder outages will just one of the de-energized network feeders be one of the four to the vault?

1. For this case $n=10$, $v=4$, $k=2$, and $i=2$. From Fig. 3, the probability read from the $k=2$, $v=4$ curves for $n=10$ and $i=2$ is $U_{10,4,2,2}=0.15$. Thus the probability that both the affected feeders in a 2-feeder outage serve this vault is 0.15. Stating this another way, only one in 6.67 2-feeder outages will involve two feeders to this vault.

Suppose that methods[3] used for computing the average frequency of occurrence for the coincident outage of two network feeders give a period of 10 years for the network in this example. Then the average number of years between occurrences of the coincident loss of two feeders to this 4-unit vault is (10) (6.67) = 66.7 years.

2. To determine the fraction of the total number of 2-feeder outages that will involve just one feeder to the vault in question, the curves of Fig. 2 for $n=10$, $v=4$, $k=2$, and $i=1$ are used. The probability for $i=1$ when $k=2$, $v=4$, and $n=10$ is $U_{10,4,2,1}=0.56$. Thus slightly more than half the 2-feeder outages will involve one of the feeders to this vault. The average number of years between occurrences for the loss of one feeder to this vault as a result of the coincident loss of two network feeders is (10/0.56) = 17.9 years.

From the preceding example it can be seen that the curves of Figs. 2, 3, and 4 serve to determine feeder-outage probabilities in individual vaults throughout the system when feeder-outage probability for the network as a whole is given. This approach, which is first to consider network-feeder outage likelihood and then vault-feeder outage likelihood, can be very useful in secondary-network system design because it readily permits quick outage-probability evaluation of alternative network plans utilizing different numbers of interlaced primary feeders and the number of network units in vaults.

Network-Protector Failure to Close

The high reliability of modern network protectors has made network-protector failure to close purely an academic consideration in the determination of coincident network-unit outages for smaller systems. For very large systems, however, the likelihood of a protector having failed to close somewhere in the system may warrant attention. Should such an outage exist in a vault where a second network unit is out of service because its primary feeder is de-energized, two network units would be coincidentally out of service in that vault.

A network protector that cannot close may be detected under two circumstances: first, customers in the vicinity of the unloaded network unit may complain of low voltage; second, during a routine inspection of network vaults the open protector will be discovered. The likelihood of detection in the first way ordinarily is small, since the open protector may be in a multiple-unit vault in which the loss of one unit does not result in overloading of the other units; or if the open protector is located in a single-unit vault, then the neighboring network transformers are fully capable of sharing load via the secondary mains without serious decrease in the voltage at customers' loads.

For a particular network system, the accumulation of reliable data on network-protector failure-to-close frequency may be impossible because of the relatively small likelihood of such occurrences when compared with the frequency of primary-feeder outages; or because infrequent or aperiodic network vault inspections make it impossible to determine the average time duration of such outages. In the absence of data accumulated for a given system, data published by the Edison Electric Institute[2–6] may be used to obtain reasonable order-of-magnitude estimates.

Equations are derived in Appendix III for estimating the likelihood for the failure to close of a network protector in a vault, or a group of units in which one, or more, other units are out of service because of primary-feeder outages. The following example will illustrate how the equations can be used.

EXAMPLE: FEEDER AND NETWORK-PROTECTOR COINCIDENT OUTAGE

Suppose that the network system in the previous example contains 100 network units. The estimated number of network-protector failures to close is one per year. The average duration of such an outage is three months.

1. During a 2-feeder outage of 66.7 years average frequency, what is the likelihood that, in a 4-unit vault that has lost two feeders, one of the two remaining units will also be unable to carry load because its network protector cannot close?

2. How often will it be that a network protector in that vault cannot close during one feeder outage in the vault of 17.9 years average frequency?

1. For this case the quantity y in equation 24 is 3 months, or 0.25 year. Substituting into 24

$$r_{(4-2)}=\frac{(2)(1)(0.25)}{100}=0.005$$

where $r_{(4-2)}=0.005$ is the years-per-year outage rate for the two remaining protectors in the 4-unit vault. Hence, from equation 25 the period of years between occurrences for the loss of three network units in the vault, as a result of the outage of two network feeders, and the coincident failure to close of a network protector in one of the two remaining units, is

$$T_{10,4,2,(2+1)}=\frac{66.7\text{ years}}{0.005}=13{,}330\text{ years}$$

2. The period of years between occurrences, for the loss of two network units in the vault, as a result of the outage of two network feeders (one of which serves the vault), and the coincident failure to close of a network protector in one of the remaining three units is found as follows: Substitute $y=0.25$ and $(v-i)=3$ into equation 24,

$$r_{(4-1)}=\frac{(3)(1)(0.25)}{100}=0.0075$$

$$T_{10,4,2,(1+1)}=\frac{17.9\text{ years}}{0.0075}=2{,}400\text{ years}$$

In the foregoing example it will be noted that the likelihood for the outage of a primary feeder to a network unit in a vault, while another network unit in that vault is out of service because its network protector failed to close, can be reduced by shortening the time duration of network protector outages. This can be accomplished by more frequent network vault inspections for testing the operation of network protectors. The average time duration of a network protector outage will be one-half the period between inspections. By substituting values for network-protector and primary-feeder outage frequency applicable to a specific system, coincident network-unit outage frequency within any given vault can be evaluated.

Conclusion

The likelihood of coincident primary-feeder outages in a network system is influenced by several determinants of network system design. These design factors also influence coincident-outage likelihood of primary feeders within the same vault or a specified group of network units. Through the use of the equations and curves presented in this paper, the probability of coincident outage of network units within any given vault, or group of units, can be evaluated from primary-feeder and network-protector outage data or experience for the network system as a whole. Such methods of probability analysis are very useful in secondary-network system planning, because they readily permit quick outage-probability evaluation of alternative network plans utilizing different numbers of interlaced primary feeders, and different numbers of network units in vaults.

Nomenclature

n = number of network feeders
v = number of network units in one vault
N = total number of network units in system
V = total number of vaults in system
$N_{n,v}$ = number of network units in an n-feeder system with v units per vault
$V_{n,v}$ = number of vaults in an n-feeder system with v units per vault

k = number of primary feeders simultaneously out of service

i = number of primary feeders out of service in one vault

r_N = network-protector failure-to-close probability for an N-unit system

r_v = network-protector failure-to-close probability for a v-unit group

a = number of network-protector failures to close per year for the entire system

y = the outage-time duration of a network protector that fails to close, years

P_k = probability for the simultaneous outage of k network feeders

T_k = average period between occurrences of the simultaneous outage of k network feeders, years

$U_{n,v,k,i}$ = the probability that a v-unit vault will have i of its feeders out of service when k out of n network feeders are out of service

$R_{n,v,k,i}$ = the probability that i feeders to a v-unit vault are simultaneously out of service

T_v = time period between failures to close of a network protector in a group of v network units, years

$T_{n,v,k,i}$ = time period between coincident outages of i feeders in a v-unit vault, years

Appendix I. Outage Probability of Feeders Serving a Vault

Suppose that attention is centered on a particular network vault, or group of network units, containing the number v units out of a total of N units, in a system served by n interlaced primary feeders. The $(N-v)$ remaining network units in the system may be considered to have imaginary boundaries encircling them such that they are all in groups of v per group. The total number of such groups is then N/v. The fraction of this total number of groups affected in the same way by a primary-feeder outage is also the probability of such a contingency occurring in the v-unit vault or group under consideration.

Consider network systems supplied by n completely interlaced primary feeders, where n may have a different integral value for each system considered

$$n=1, 2, 3, 4, \ldots \tag{1}$$

Suppose that in each system, the network units are in groups of v, where v may have any integral value

$$v=1, 2, 3, 4, \ldots \tag{2}$$

No two units in a group of v may be served by the same primary feeder. In an n-feeder system containing groups of network units with v units in each group, there is a maximum possible number of groups for which no two groups will be served by the same combination of v out of n feeders. This number of different groups is given by

$$V_{n,v}=\frac{n!}{v!(n-v)!} \tag{3}$$

The total number of network units in $V_{n,v}$ vaults, each containing v units, is

$$N_{n,v}=V_{n,v}(v) \tag{4}$$

The quantities n, v, $N_{n,v}$ describe a hypothetical secondary-network system served by n primary feeders. Each vault contains v network units, with each unit in that vault supplied by a different feeder. The total number of vaults in the network is $V_{n,v}$ and the total number of network units is $N_{n,v}$.

The n network feeders will suffer outages such that any number k out of n feeders may be out of service at the same time, where

$$k=1, 2, 3, \ldots \tag{5}$$

When the coincident outage of two or more network feeders occurs, various vaults throughout the network area will have none, one, or more of their feeders de-energized. During such a concurrent outage of k network feeders, let i be the number of de-energized feeders in a v-unit (or v-feeder) vault, where

$$i=0, 1, 2, 3, \ldots \tag{6}$$

Two limitations are placed on the maximum value of i

$$i \leq v \text{ or } i \leq k \tag{7}$$

In this hypothetical $N_{n,v}$-unit, $V_{n,v}$-vault, n-feeder network system in which each vault houses v units, the fraction of the total number of vaults in which i feeders are lost during a network-wide outage of k feeders is represented by the symbol $U_{n,v,k,i}$ where

$$1 \geq U_{n,v,k,i} > 0 \tag{8}$$

The fractional number $U_{n,v,k,i}$ is the probability that a v-unit vault in an n-feeder system will lose i out of v units as a result of a coincident outage of k out of n feeders.

Fig. 5. Four different, hypothetical 6-feeder network systems. The first system has vaults containing one unit each (v = 1); the second system, two (v = 2); the third system three (v = 3); and the fourth system four (v = 4). For each system, all the different possible combinations of feeders serving vaults are tabulated. From such tabulations, the fraction of the total number of vaults affected by various primary-feeder outages can be observed. This fraction is also the probability of any one vault being so affected

$U_{n,v,k,i}$ in terms of the two network design parameters n and v; the number k of network feeders simultaneously out of service; and the number i of affected feeders to a specific vault or group of network units.

To illustrate how such equations may be developed, consider the case of 6-feeder networks ($n=6$). Four different 6-feeder systems will be examined. In the first system, network units are individually located ($v=1$). In the second they are in pairs ($v=2$). In the third and fourth systems, network units are arranged in groups of three ($v=3$) and four ($v=4$) respectively. For all systems let the six primary feeders be numbered I, II, III, IV, V, and VI. Fig. 5 lists all the different combinations for six feeders serving vaults containing one, two, three, or four network units, such that in each system no two vaults are served by the same combination of feeder numbers.

After the possible combinations of feeders serving a vault with v network units are tabulated as in Fig. 5, the number of vaults losing i units when k out of six feeders are lost can be obtained by inspection. From an examination of other cases similar to those tabulated in Fig. 5, but for other values of n and v, the following equations are obtained:

For $k=1$, $i=1$

$$U_{n,v,1,1}=\frac{(n-1)!}{(V_{n,v})(v-1)!(n-v)!} \tag{9}$$

For $k=2$, $i=1$

$$U_{n,v,2,1}=\frac{2(n-2)!}{(V_{n,v})(v-1)!(n-v-1)!} \tag{10}$$

For $k=2$, $i=2$

$$U_{n,v,2,2}=\frac{(n-2)!}{(V_{n,v})(v-2)!(n-v)!} \tag{11}$$

For $k=3$, $i=1$

$$U_{n,v,3,1}=\frac{3(n-3)!}{(V_{n,v})(v-2)!(n-v-2)!} \tag{12}$$

For $k=3$, $i=2$

$$U_{n,v,3,2}=\frac{3(n-3)!}{(V_{n,v})(v-2)!(n-v-1)!} \tag{13}$$

For $k=3$, $i=3$

$$U_{n,v,3,3}=\frac{(n-3)!}{(V_{n,v})(v-3)!(n-v)!} \tag{14}$$

Values for $U_{n,k,v,i}$ computed from equations 9 through 14 are plotted in the curves of Figs. 2, 3, and 4. These curves show the probability ($U_{n,k,v,i}$) for losing i out of v feeders in a given vault should k out of n network feeders suffer coincident outages.

Suppose that the probability for the simultaneous outage of k network feeders is P_k. Methods for obtaining P_k are discussed in the first probability paper.[2] Then the probability for i feeders to a v-unit vault being simultaneously out of service because of coincident feeder outages is

$$R_{n,v,k,i}=(P_k)(U_{n,v,k,i}) \tag{15}$$

In the previous paper[2] the average number of years between occurrences of the coincident outage of k network feeders is called T_k. Hence for an individual vault, or group, containing v network units, the period in years between occurrences for the coincident outage of i network units because of k simultaneous network-feeder outages is

$$T_{n,v,k,i}=\frac{T_k}{U_{n,v,k,i}} \text{ years} \tag{16}$$

Assumptions

The analyses in Appendixes II and III are approximate, and are based on the following assumptions:

1. The total number N of network units in the system remains constant regardless of the number of primary feeders or network units out of service, i.e., $N>>1$.
2. Over a very long period of time, each network protector will experience the same number of failures to close of equal time duration.

Appendix II. Probability of Network-Protector Failure to Close

Consider a network system with a total number of N network units. For most systems in which coincident-outage probability is sufficiently large to warrant consideration, a single network unit represents a small fraction of the total number employed, i.e., $N>>1$. It will be assumed that the loss of one, or even several, network protectors still leaves very nearly the same total number in service. Hence for the purpose of the following analysis it is assumed that

$$N\cong(N-1)\cong(N-2), \text{ etc.} \tag{17}$$

For the entire system, let the number of network-protector failures to close be the quantity a per year. Then the average failure-to-close rate per protector is a/N per year. The average number of years between failures, for a given protector, located anywhere in the system is N/a years.

Let the average time interval between inspections of a network protector be ($2y$) years. Assuming that a protector discovered unable to close is immediately repaired or replaced, the average length of time during which a faulty protector remains open is y years. Hence the probability that somewhere in the system a network protector is open because it cannot close is

$$r_N=a(y)=ay \tag{18}$$

If attention is centered on a particular v-unit vault, then the failure-to-close probability for the network protectors in that vault is

$$r_v=\frac{v}{N}r_N \tag{19}$$

Substituting equation 18 into 19,

$$r_v=\frac{vay}{N} \tag{20}$$

When it fails to close, a network protector will remain open y years. Hence the average number of occurrences per year in a v-unit vault is

$$a_v=\frac{r_v}{y}=\frac{vay}{N}\left(\frac{1}{y}\right)=\frac{va}{N} \text{ occurrences per year} \tag{21}$$

The period between such occurrences is

$$T_v=\frac{1}{a_v}=\frac{N}{va} \text{ years per occurrence} \tag{22}$$

T_v is the average number of years between the occurrence of a network-protector failure to close in a group of v units in a system of N network units experiencing the quantity a network-protector failures to close per year.

Appendix III. Primary-Feeder and Network-Protector Coincident Outage

The average time period between occurrences of the coincident outage of i primary feeders to a v-unit group is given by $T_{n,v,k,i}$ years in equation 16. From equation 21 the number of occurrences per year for the failure to close of one of the network protectors in the remaining $(v-i)$ units in that v-unit group is

$$a_{(v-i)}=\frac{(v-i)a}{N} \text{ occurrences per year} \tag{23}$$

The duration of each such occurrence is y years. Hence the total time, in years per year, that such a condition will exist in the group of $(v-i)$ units is given by the probability

$$r_{(v-i)}=a_{(v-i)}y=\frac{(v-i)a}{N}(y)$$

$$=\frac{(v-i)ay}{N} \text{ years per year} \tag{24}$$

Hence the average period between occurrences involving the coincident loss of i primary feeders and one network protector out of the remaining $(v-i)$ units in a v-unit group is

$$T_{n,v,k,(i+1)}=\frac{T_{n,v,k,i}}{r_{(v-i)}} \text{ years} \tag{25}$$

Discussion

G. H. Arapakis (Consolidated Edison Company of New York, Inc., New York, N. Y.): Referring to equation 15, this expression gives the outage probability of finding one or more network units in a v-unit vault out of service due to the outage of one or more feeders from a group of n feeders to a network area. However, the author fails to point out that if we wish to find the total probability of i units out of service in a v-unit vault, and this is the result of practical interest to us in system design, the expression given by equation 15 must be summed up for values of $k=i$ to $k=n$ as follows

Probability of i units out of service in a v-

$$\text{unit vault} = \sum_{k=i}^{k=n} R_{n,v,k,i}$$

$$= \sum_{k=i}^{k=n} (P_k) U_{n,v,k,i}$$

For example, in a network area supplied by a total of 10 feeders, to find the probability of one unit out of service in a 4-unit vault it would require theoretically the summation of nine terms, although practically the summation of the first two or three terms yields a sufficiently accurate answer. Similarly the probability of two units out of service will require eight terms, etc.

I would like to point out, however, that in a v-unit vault supplied by v number of different feeders, the total probability of one or more network units out of service due to feeder outages can be calculated very simply on the basis of the outage probability of the v-feeders supplying this particular vault, independently of the n feeders to the network area, as follows

Total probability of i units out of service in a v-unit vault due to feeder outages

$$= \frac{v!}{i!(v-i)!} p^i (1-p)^{v-i}$$

where $p =$ average outage probability of any one feeder from accidental causes. (This will depend on the average length of a feeder, and therefore on the size and extent of the network area.) This expression should equal to the summation of terms given in this discussion. While I have not proved this equivalence in general terms, I am satisfied that it is true from a number of numerical examples for which I have compared the two expressions.

In general, as I have pointed out, we are interested only in the total probability of finding one or more network units out of service in a particular vault. While the mathematics developed by the author are correct, I do not see what is to be gained by breaking up this total probability into a summation of terms when it can be calculated very simply and very quickly as one term from the equation which I have given here.

David N. Reps: Mr. Arapakis points out an important addition to Appendix I. The curves of Figs. 2, 3, and 4 give the first three terms of the summation to obtain the total probability for finding i out of v feeders to a given vault out of service. For example, in a 4-unit vault in a 10-feeder network the summation representing the total probability for finding one feeder out of service would be

$$\sum_{k=1}^{k=10} (P_k)(U_{10,4,k,1}) = (P_1)(U_{10,4,1,1}) +$$

$$(P_2)(U_{10,4,2,1}) + \ldots + (P_{10})(U_{10,4,10,1})$$

From Fig. 2, $U_{10,4,1,1}=0.4$; from Fig. 3, $U_{10,4,2,1}=0.55$; from Fig. 4, $U_{10,4,3,1}=0.5$. Thus the first three terms of the summation become

$$\sum_{k=1}^{k=3} (P_k)(U_{10,4,k,1}) = 0.4P_1 + 0.55P_2 + 0.5P_3$$

Mr. Arapakis also points out, and correctly so, that the terms containing P_k for $k>3$ add negligibly to the summation, because the probability for having more than three feeders simultaneously out of service is extremely small.

The reasons for my having chosen the particular way in which I present network-vault multiple-outage probability methods are severalfold. Much of the work that is being done in secondary-network system engineering design and economic analysis involves consideration of higher secondary voltages, multiple-bussing of network units, and higher primary-feeder voltages. Such changes are best investigated through the use of what I call "hypothetical equivalent" systems which exist only on paper, but over which the engineer has full control of the variables. One extremely important variable of network design is the number of primary feeders. For instance, increasing the feeder voltage permits the use of a fewer total number of feeders. This change affects not only network design and cost but also feeder-outage probability. The approach I have taken in presenting network-feeder and network-vault outage probability information lends itself to use in the comparison of alternative network designs. Such an approach not only permits answering the question "What will happen in an existing network system?" but also "What will happen in a network system that does not yet exist?"

Mechanical Alignment of Vertical-Shaft Hydroelectric Units as Practiced by Tennessee Valley Authority

C. L. NORRIS
NONMEMBER AIEE

DURING the past 20 years the Tennessee Valley Authority (TVA) has purchased and installed 74 hydroelectric generating units in 21 different power plants. Three additional units and two additional plants are under construction.

These machines vary in capacity from 7,000 kw under a head of 58 feet to 67,500 kw under a head of 330 feet. Some idea of their size can be obtained from the dimensions shown in Fig. 1. The manufacture and installation of each of these machines has followed a more or less standardized procedure as set up by the TVA personnel. This procedure provides limited running tolerances in shop machining of the shafts and thrust-bearing parts. It also provides a limited misalignment tolerance after the unit is completely assembled in the field.

Design and Specifications

Each machine is of the vertical-shaft type with the thrust bearing located below the rotor and resting on the heavy structural lower bracket of the generator which spans the turbine pit and supports the entire rotating elements. A main-shaft guide bearing is located in the turbine head cover immediately above the turbine runner; a second one is located just below the generator rotor in the generator bearing bracket. In a few cases a third is located in the generator upper bracket directly above the rotor.

The correct alignment of a hydroelectric unit begins with the inception of the job and is completed when the last part is in place. To have a correctly aligned machine the controlling tolerances and procedures must be enumerated in the manufacturing and installation specifications.

Since the majority of the machined surfaces which could cause trouble are a part of the generator contract, the generator manufacturer is usually made responsible for the shop-checking of the

Paper 55-163, recommended by the AIEE Power Generation Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted October 18, 1954; made available for printing December 3, 1954.

C. L. Norris is with the Tennessee Valley Authority, Knoxville, Tenn.

The author is indebted to R. A. Hopkins, head electrical engineer, Division of Design, Tennessee Valley Authority, for his guidance in the preparation of this paper.

combined shafts and the thrust-bearing parts. Because it is a physical impossibility to machine all mating pieces to zero tolerances, the turbine and generator shafts are checked in more than one relative position and when the best possible combination is determined each piece is match-marked at the coupling so that this same relation can be obtained when the field assembly is made. In addition to this, the generator manufacturer is made responsible for the final field alignment of the rotating parts.

Turbine Erection

For each machine the turbine has been purchased for installation by the TVA forces and the generator has been purchased installed by the generator manufacturer. Prior to start of erection the Authority submits to each interested party copies of a suggested method of erection for comments and suggestions. The differences, if any, are ironed out and in this manner erection procedures and methods which are satisfactory to all parties are outlined in advance.

Because a good alignment of machines of this type necessarily includes the embedded parts and because once the parts are embedded it would be extremely expensive to change them, the construction specifications treat each piece in detail, usually giving the size, weight, and relation to control lines and elevations. If special bracing or bolting is required this is discussed in detail, with necessary references to drawings. No concrete forms, braces, or rods are allowed to come into physical contact with the part or parts being embedded. Concrete vibrators are not allowed to be used in areas where there is danger of the vibrator striking the supporting jacks, screws, rods, braces, or the part itself. During the pacing of the concrete around the embedded parts it is usually necessary to spray water on the inside surfaces of the parts in order to hold to a minimum the distortion caused by the heat of the setting concrete. Concrete placement schedules are arranged to minimize this heat and any unbalanced thrusts. Periodic checks of the plane and concentricity of the parts are made as the erection progresses. To the uninitiated it might appear that such caution is unnecessary, but some of the necessity for good alignment can be appreciated when it is realized that the horizontal running clearances between the turbine runner and the stationary parts range from 12 to 125 mils and that normal relative speeds between these two parts range up to 75 miles per hour for some of the smaller clearances.

Once the embedded parts are in place, the remainder of the machine should be installed around these parts; therefore the turbine runner is set in place in the best possible relation with the embedded parts. The turbine shaft is set plumb and the face of the top flange level. The turbine runner and shaft are usually set about 0.750 inch below the final running position and are supported in this position by brackets built in the head cover for this purpose on propeller turbines and by the lower part of the runner which rests on a flange in the embedded parts on Francis turbines. The distance below the final running position is determined exactly by measuring between two machined surfaces in the turbine assembly. This dimension is used by the generator erector in placing the generator parts at the correct elevation.

Generator Erection

With the foundation concrete in place and with the turbine parts installed as just outlined, the generator manufacturer can proceed with the erection of the generator parts using the location of the turbine shaft flange as a control point for both horizontal and vertical dimensions, irrespective of previously established control lines or datum planes.

The soleplates for the generator-bearing bracket are set in place and grouted in using the position of the top flange of the turbine shaft to determine the location, both vertically and horizontally.

The generator-bearing bracket, shaft, and thrust-bearing assembly is made in the erection bay or on some convenient floor accessible to the powerhouse crane. For this purpose the bearing-bracket is placed on simulated soleplates and the shaft and thrust bearing are installed with the shaft resting on the thrust bearing. After the bearing and shaft have been adjusted and positioned with respect to the bracket, the entire assembly may be set in place on the permanent soleplates. The exact location of the generator shaft is determined from the position of the turbine shaft flange which has been accurately located prior to the generator erection.

When the generator shaft is in position directly above the turbine shaft and at the correct elevation, the generator shaft is rotated so that the shaft flanges can be bolted together in the same relative position, as indicated by the factory-placed match marks. To prevent damage to the permanent bolts the two flanges should be pulled together with temporary, loose-fit bolts, with the use of at least half as many bolts as there are bolt holes in the flanges. When the flanges are together the permanent bolts are installed and prestressed by stretching so that the torque necessary for any condition of loading can be transmitted through the coupling by the friction on the flange faces.

The combined shafts are then set vertical with the turbine runner positioned correctly with respect to the stationary parts, the generator stator is centered about the top portion of the generator shaft and the stator frame is bolted to the previously placed soleplates. With the stator round and correctly located, the soleplates are grouted in. The dowels between the soleplates and the stator frame are installed after the final alignment is completed.

The rotor, previously assembled in the service bay, is set in place and bolted to the generator shaft. Care must be exercised in placing the rotor so that the stator coils are not damaged. When the generator erection is completed, but before the guide bearings are set, and thrust pot closed, or the rotation check made, the thrust shoes are checked for equal loading. This should be done by an approved method acceptable to the customer and the manufacturer. To avoid the disadvantages involved in tilting the bearing bracket to plumb the shaft assembly, the shoe loading should be done in such a manner as to leave the shaft vertical and at the correct elevation

Fig. 2. Rotation check data

when the loading adjustments are completed.

Rotation Check

When the generator parts are assembled and aligned and the shafts are coupled together it is essential that a mechanical, step-by-step rotation check be made of the entire rotating element. To make this check accurately it is necessary to hang four heavy plumb bobs around the shaft at the 90-degree points. Each bob is suspended in oil by a fine piano wire which extends over as much of the length of the combined shaft as possible. The wires supporting the bobs should be approximately the same distance from the shaft (±1/4 inch), and located so that they will not interfere with the rotating elements when the shaft is being moved from one position to the next. The arrangement should be such that a tram rod can be used in conjunction with a flashlight battery and a set of head phones so that the operator can tell when the smallest possible reading is obtained between the shaft and the wire.

At the zero position readings are taken from the shaft to each plumb wire at a minimum of three different elevations. This will determine whether or not the shaft assembly is straight and vertical. The rotating element is then turned mechanically 90 degrees at a time and similar readings are taken at the 90-, 180-, 270-, and 360-degree positions. To avoid excessive side movement or sliding on the thrust-bearing surface it has been found desirable to set up four guide shoes while the element is being turned; these shoes are to be backed away from the guide surface before readings are taken.

To avoid errors in reading the micrometers and in recording, it has been found desirable to check the quantities by adding opposite readings (see the tabulation in Fig. 2; the sum of $N + S$ or $W + E$ = the same for each position from zero through 360 degrees at any given elevation) and by plotting the shaft centers as each check is made. It is extremely important that the rotating element be free from any outside interference and that it is hanging free from the thrust bearing during the period when check readings are being made.

Fig. 2 shows a typical rotation check arrangement with check readings and results. It will be noted that in this case the shaft center, as determined from the plumb bobs on opposite sides, describes a throw-out circle on the lower end of about 0.0055 inch and that the shaft is straight from top to bottom.

The maximum throw-out as determined by this method is limited under the generator contract to a quantity determined by

$$T = 0.00075\,(L/R)$$

where

T = throw-out circle diameter, inches
R = radius of thrust-bearing runner plate, inches
L = length of shaft, inches (lower face of runner plate to center of turbine guide)

If the shaft throw-out is limited to the amount allowed by this equation the shaft alignment will usually be satisfactory; however, in no case is the actual throw-out circle allowed to be as much as the minimum clearances between the turbine runner and the stationary parts.

If the throw-out circle is greater than either of these above quantities, the remedy for each individual case is decided as the occasion arises. However, two of the more common remedies are: 1. rotating the runner plate with respect to the thrust collar, and 2. tightening the coupling bolts on one side of the coupling flanges.

When the throw-out circle has been determined, the main-shaft guide-bearing centers are set so that the shaft center will be held in the center of the throw-out circle and vertical within a tolerance of 0.001 inch in each 5 feet of shaft length.

With the shaft in the final position and with the guide bearings in place, reference points are established in the turbine head cover and the generator main bearing bracket. These points are carefully placed so that they are all equidistant from the shaft surface and readily accessible for future use without excessive dismantling of the unit parts. Records in triplicate are kept of all important settings, clearances, and tolerances.

Immediately following the completion of the assembly a thorough and complete inspection of the entire unit is made by all interested parties to determine that the unit is in starting order. All starting procedures, tests, etc., are under the direction of a co-ordinator who is familiar with the construction, erection, and operation of the machine.

During the mechanical run it is determined if the generator rotor will require additional weights for balance. If balancing is required it is desirable that this be done before the heat run is started.

Conclusions

The satisfactory and successful operation of any mechanical unit requires good alignment of the various parts.

Assuming a correct design, any installation in which the mechanical alignment is correct will give trouble-free service mechanically, whereas an installation which is not in correct alignment will give continuous trouble in the overheating of excessively worn parts, overstressing, fatigue, and it may be a contributing factor to many other troubles.

Good alignment raises production and lowers production cost due to reduced outages for expensive maintenance and repairs. Good alignment can be obtained at little or no extra cost with proper scheduling.

◆

Discussion

William J. Rheingans (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The paper is a timely one, since the hydraulic turbine sections and the large generator and converting apparatus section of National Electrical Manufacturers Association are now working on standards for the alignment of vertical hydroelectric units. Since one of their problems is the question of rotational checks, it was interesting to note that the TVA insists upon rotational checks for all their units as a means for determining proper alignment.

The author's remarks regarding proper scheduling of parts and proper alignment checks in the shops are of great importance in obtaining proper alignment of vertical-shaft hydroelectric units.

J. F. Roberts (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): This paper is an indication of the amount of careful work that the TVA has done in connection with its great number of hydroelectric installations.

As units get larger and larger, it becomes more and more difficult to hold to extremely accurate tolerances which are required, particularly in thrust-bearing surfaces and coupling faces. It is only by taking greater care, as outlined in the paper, and carefully checking these units before they go into operation that satisfactory operating results can be obtained. If such precautions are not taken, then the penalty is either excessive wear on turbine and generator bearings, or excessive strain with possible mechanical troubles or even broken shafts at a later date.

The success which the TVA has had by developing this method of alignment and rotation checks has been a tremendous help to the industry, and similar methods are being adopted by many other users of this type of equipment. It is particularly desirable when one part of the equipment, such as the turbine, is furnished by a different manufacturer from the generator. A careful check of this type serves to locate the source of any minor inaccuracies and they can be corrected before any troubles arise, and without setting up a 3-way argument between the various manufacturers and the customer.

The tolerance for shaft throw as given by the equation in the paper is practical on shafts which are relatively short but, as the author points out, on long shafts this may result in a possible tolerance greater than the bearing clearance, in which case we must either rely on flexibility of the shafts and some bending, or else the scraping of the thrust-bearing surface, in order to get even closer tolerances.

J. Fisch (S. Morgan Smith Company, York, Pa.): The procedure used by the TVA has been applied to numerous installations. It is assumed that it has given satisfactory results in all cases. The practice noted in the section "Turbine Erection" to work out, in advance, a method of erection satisfactory to all parties concerned is to be highly recommended. No doubt progress of field work can thus be accelerated and kept under good control.

In one section "Generator Erection" temporary bolts are prescribed to pull the coupling flanges together. It is believed that this is an unnecessary refinement when the final bolts are machined to provide 2 to 3 mils' clearance in the flange holes in accordance with American Standards Association standards.

As noted in the section "Rotation Check," straightness of the shaft is determined from the four wires with plumb bobs. During rotation, wire readings are necessary only at the zero- and 360-degree positions. The throw-out circle at the turbine bearing can be established by "milking" from trammel points in the bearing housing during the four positions.

It should be mentioned that all of these alignment checks are made before the rotor is dynamically balanced. Balancing may affect the painstakingly obtained initial alignment.

Rotation checks apply primarily to units with Kingsbury-type thrust bearings. Extreme care must be exercised when rotating large units in order to avoid thrust-bearing damage.

Numerous units with spring-type thrust bearings have been installed without rotation check. After plumbing of the shaft, the unit is brought up to speed and the rotor balanced. During coasting down in speed, measurements with indicators are taken on two of the stationary thrust-bearing shoes to determine the vertical oscillations or wobble. This wobble is an indication of the perpendicularity of the thrust runner face with the shaft axis. Experience has shown satisfactory operation if the measured amplitude of the wobble does not exceed 0.002 inch.

R. B. McKeeby (General Electric Company, Schenectady, N. Y.): The author has made a worth-while contribution to a subject on which there is little published information. There has been real need for a method which could be applied practically in the over-all alignment of the hydroelectric unit. Not so long ago, the industry relied on a relatively few seasoned and experienced erectors, most of whom were in the employ of the turbine or generator manufacturers. These men command our respect for their accomplishments, which were often made under very difficult local conditions. The majority had many years of training, and were experts in their field. Men representing the two manufacturers would turn over to the operators a satisfactorily operating unit. They kept records but these were usually closely guarded and not accessible to the operating and maintenance people, who were thus left with very little knowledge of the unit they would be expected to maintain.

For this and other reasons an industry standard is needed to cover the erection of hydroelectric units. I am sure that the author's paper will encourage others to record their practical experience in this field, thus leading eventually to an industry standard.

The paper deals with vertical-shaft units where the thrust bearing is located below the generator rotor and with only the adjustable shoe type of bearing, one of the four types of thrust bearings in use today. The TVA has nine units using the spring thrust bearing which is not adjustable.

The author devotes considerable space to the difficult and time-consuming rotational check. We have found that rotational checks improperly conducted sometimes give misleading information. In some cases, this procedure has failed to reveal a misalignment, and the result has been the formation of iron oxide which cannot be tolerated in any thrust-bearing housing. It is not uncommon to find slow speed rotors of large diameter out of balance as much as 200 pounds on completion of the assembly work. We have demonstrated on several units that placing 200 pounds on the rim of a rotor when the shaft is hanging free and supported only on the thrust bearing will cause the turbine guide-bearing journal to swing out of position 10 to 20 mils. This is due principally to the flexibility of the thrust-bearing supporting bracket. If a rotational check is made on such a unit before it is balanced, the results can be meaningless, even though a satisfactory throw circle is indicated. The subsequent addition of balance weights will tip the rotor enough to generate a throw circle of 20 to 40 mils. Thus, we cannot rely on the throw circle for an indication of the runout of the thrust runner, or straightness of the shaft assembly, until the rotor is in static balance. Assuming the entire unit to be in static and dynamic balance, the displacement of the shaft, indicated by the throw circle will be restrained during operation by the turbine guide bearing, in turn causing a tipping of the thrust bearing and resulting in unequal loading of this bearing as the unit rotates. When excessive, this condition usually causes fretting corrosion on some or all of the surfaces between the thrust-bearing runner and the thrust block. The iron oxide thus formed has caused thrust-bearing failures.

The results of a rotational check are of some value if made on a unit after it has been in satisfactory operation where it is known that the generator and turbine rotors are in good balance. This method has been used for many years in locating trouble spots in a unit in operation for some time.

Several unsuccessful attempts have been made to make rotational checks on larger units. It must be realized that today there are in operation units where the total weight of the rotating element is over 2,000,000 pounds and the thrust bearing is designed to support a load of over 4,000,000 pounds. All these factors must be kept in mind in planning for the future in regard to an industry standard for checking the alignment of these units.

It is not my intention to be critical. The TVA has a large number of hydroelectric units in service, and their operating record speaks for itself. The importance of the subject justifies more papers such as this, freely discussing alignment techniques.

R. A. Baudry (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The author must be commended for his clear and concise presentation. It is interesting to note that all the 74 units discussed have the thrust bearing located below the rotor, and that also most of the generators have only one guide bearing located below the rotor. This type of generator, usually called the umbrella type is well suited to accurate alignment of the rotating parts, particularly when provided with a thrust collar forged integrally with the shaft, which makes it possible to obtain easily the small throw-out specified by the author. The specified value of the throw-out indicates that the periphery of the thrust-bearing runner must have a maximum throw-out of only 0.00075 inch with respect to the centerline of the shaft. This is indeed a very small value when it is considered that some of the thrust collars are nearly 9 feet in diameter. Such a small tolerance is made possible only by the use of the most accurate type of machine tools and methods of quality control.

The tolerance of 0.001 in each 5 feet of shaft length for deviation from a vertical line indicates the high standard of quality requested by the author in the erection of machines. It would be of interest to know how this variation from a vertical line is affected by changes of the foundation with time and whether a larger variation from the vertical affects the operation of the unit as long as the guide bearings are well centered with respect to the shaft.

P. S. Johrde (Elliott Company, Ridgeway, Pa.): Since the erection procedures outlined have been tried and proven on such a wide size range of machines, they should be of interest to a great many people.

Undoubtedly, several deviations in these procedures could be brought out but these would probably be minor departures from the general line of action. We can point to a few cases where shifting foundations or the whole power plant have thrown an entire turbine-generator unit considerably out of plumb with no harmful effect upon operation. On the other hand, there are cases where the misalignment from foundation shifting was detrimental to operation. We dare not minimize the importance of alignment.

The erection procedure is for the umbrella-type of generator only. I would like to enlarge upon the subject to point out that the rection of an umbrella-type generator and its turbine can be co-ordinated to result in less total erection time than is the case with a suspended type of generator and turbine of the same rating.

Let us consider a large unit the stator of which was shipped in several sections with most of the coils installed at the factory. The lower bracket and stator soleplates can be grouted in with the aid of surveyors' instruments as soon as the foundation will permit. In both types of unit the horizontal and vertical location will have to be determined from machined stationary parts of the turbine. In either case the stator can be assembled and placed temporarily on its soleplates for completion of the winding. Meanwhile, the rotor is assembled and the turbine assembly can proceed if the scaffold for the armature winders is of the balcony type, which leaves most of the pit open for access to the turbine. Simultaneously with the rotor and stator work, the umbrella machine's lower bracket, thrust, and guide-bearing assembly, and shaft can be assembled in an erection area.

With a suspended type, the upper bracket and possibly part of the thrust bearing, upper guide bearing, and oil pot assemblies can be put together at this time.

From then, the umbrella construction proceeds speedily as outlined by the author. In pyramid fashion, the basic assemblies go together with center and levels being transferred from assembly to assembly. Finally, the upper bracket and exciter(s) are put in place using the generator rotor hub or shaft as center.

The center alignment of the stationary assemblies of the suspended type, on the other hand, should be done with the aid of a tight wire by placing the lower bracket, stator, and upper bracket assemblies in operating position with reference to the turbine shaft.

The upper bracket must then be removed and the rotor lowered into the stator until it rests on the hydraulic jacks in raised position. Next, the upper bracket is put back in place; the thrust block and bearing parts are assembled and the rotor is lowered so that it hangs on the thrust bearing.

From this operation on, the shaft coupling-up, aligning, and rotation check are accomplished approximately as described in the paper. The exciter(s) can then be positioned using the generator shaft or thrust block as center. In general, after comparing the erection of the two type generators, we can say that the umbrella type of generator and turbine required less elapsed erection time because:

1. More man hours can be spent simultaneously on the generator and turbine, i.e., less work is needed after the turbine shaft is set in position.
2. Less handling of large parts is required.
3. There is no necessity for centering all stationary elements and then disassembling part of them in order to place the rotor.

C. L. Norris: We appreciate the interesting and constructive remarks presented by the discussers. Mr. Rheingans has properly emphasized the importance of shop scheduling and alignment checks. We agree with Mr. Roberts' comment regarding the equation and also with his observations in regard to the advantages of preoperation checking.

Mr. Fisch questions the necessity for using undersize bolts for pulling coupling flanges together where American Standards Association fits are used. Using undersize bolts gives maximum assurance that the regular coupling bolts will not be scored or the nuts damaged. We have also used alternate methods such as jacking on the coupling flange and using long undersize bolts, a strong-back, and hydraulic jacks between pairs of volts. Both alternate methods are quite rapid but require additional equipment and careful planning to avoid excessive coupling flange deflection. We believe the tramming to four wires gives maximum accuracy as to the diameter and location of the shaft throw-out circle as compared to tramming to the bearing housing.

The comment in regard to the use of an indicator to measure shoe oscillations on a spring-type bearing is informative. We have not had sufficient experience with this method to evaluate its usefulness.

Mr. McKeeby's comments in regard to the erectors and their closely guarded records are in order. These gentlemen decidedly deserve credit for their skill and knowledge. We do not agree that the methods outlined in the paper apply only for one type of bearing since they have been successfully used on both the Kingsbury flat-adjustable shoe and on several spring-supported type bearings. The usual precautions taken to avoid unequal weight distribution when assembling the rotor rim have been found to give a rotor balance such that the rotation check is not materially affected provided the methods outlined in the paper are followed.

Mr. Baudry's observations are interesting in regard to shop practices required to meet close tolerances. We have operated units that do not conform to the 0.001 inch in each 5 feet of shaft length, but believe that better over-all alignment is obtained if this tolerance is maintained during the initial assembly.

Mr. Johrde's comments, comparing erection procedures of the conventional design with the umbrella-type of generator, are valuable. As stated, the paper is based on the umbrella type.

A Look to the Future of Power Transmission in the West

H. D. HUNKINS
ASSOCIATE MEMBER AIEE

A LOOK to the future of electric power markets and resources in the western states shows several problems different from those in the eastern states. These problems offer a special challenge to engineers. In contrast to the East where most load areas adjoin one another, the West is composed of widely separated load areas located in drainage basins where the economies which could not be sustained by the natural rainfall are supported by use of water from mountainous areas. Coal, used to produce most of the eastern power requirement and in many cases relatively close to major market areas, is also abundant in the West, but is located a considerable distance from the basin markets. Hydro power has in the past supplied most of the western needs, but in some areas the electric load has already exceeded this resource.

It appears desirable that the electrical industry continue investigations of comparing electric transmission with other means of transporting energy stored in the conventional fuels until economic production from other sources, such as atomic and solar energy, and tide and wind action, is assured in sufficient quantities to obviate this need. Of the four possible new sources of energy, production from nuclear reactions appears to offer the most promise.

The power demands in the Northwest have been met almost entirely from hydro power, while in northern and southern California the industry has had to produce in increasing amounts power from steam plants largely supplied by oil and natural gas transported through pipe lines. However, the future use of these fuels in enormous quantities under boilers may be limited by such already apparent factors as increasing cost of exploration, estimated future demand in relation to new discoveries, and increasing value of these resources for other uses. That these factors are recognized is shown by the fact that new west-coast power plants are being built with provisions for burning coal.

Atomic fuel having the highest energy content per pound would appear to be ideal from the standpoint of transportation over great distances in the West, if and when production costs become competitive with energy produced from hydro and conventional fuels.[1] When it is considered that atomic production of electric power is not now competitive and may face a relatively long period of development in comparison with the time it takes the electric load to double, at present rates of growth about 10 years, it appears advisable to investigate the use of the large supplies of western coal which lie along the Rocky Mountains.

As an example, consider the southern California load center which is taken as the principal load concentration in an area including Arizona and southern Nevada. Assuming continuation of the long-time growth rate, it may be necessary to supply by 1975 from thermal generation the difference between 12,500,000-kw peak load and 3,100,000 kw of hydro power representing the ultimate hydro development for this area. In 1950, the peak load was 3,900,000 kw with 2,320,000 kw supplied from hydro resources.

The estimated annual energy requirement would be approximately 71.2 billion kw-hours, including some 16.4 billion kw-hours supplied from falling water. The balance, or 54.8 billion kw-hours, if supplied from thermal generation using coal, would require about 22,500,000 tons of coal annually. Fig. 1 shows the location of coal resources in eastern Utah with existing rail lines and possible transmission-line routing to southern California.

Coal, or oil and gas made from coal, could be transported to power plants in southern California by several methods, among which shipment by rail appears at present to be the only practical one. Coal has been moved comparatively short distances by hydraulic pipe line using a water carrier, and by conveyor belt, but these methods are not considered practicable for the long distance and type of terrain involved. The conversion of coal to oil or gas for pipe-line conveyance as developed today is still too inefficient to compete economically with moving energy either by rail or by transmission line. A large portion of the energy in coal would be lost in the conversion, and gas produced from coal has too low a heat content for economical long-distance transportation. The status of these alternative methods would normally be reviewed in the light of possible new developments although no present justification is apparent.

Cost of Hauling Coal by Rail

Several excellent papers have been published which make a general comparison of electric transmission versus methods of transporting fuels.[2-4] A problem of concern has been the proper charge for hauling coal. It appears desirable to use specific freight rates for the transmission scheme and the rail haul under comparison.

Following are 18 principal factors used by the Interstate Commerce Commission in determining freight rates:[5]

1. Cost of service to the carrier.
2. Value of service to the shipper.
3. Value of the article.
4. Nature of the article—whether crude or finished, liquid or dry, etc.
5. Risk in handling the article.
6. Distance of haul (mileage scales).
7. Bulk (size) and weight of the article (density).
8. Whether special facilities or extra services are required.
9. Expense at terminals.
10. Volume of traffic, and periods of movement.
11. Method of packing and protecting the article.
12. Rates on similar articles moving under similar circumstances and conditions.
13. Rates of competing carriers.
14. Competition between producing centers or markets.
15. Whether or not the rate will be conducive to an increasing movement of the article.
16. Prospects of cars being returned loaded or empty.
17. Rates account fourth section of the Interstate Commerce act.
18. Loading (per car).

An exhaustive study should be made considering how these factors have been interpreted. Item 13 indicates that the existence of or obvious feasibility of competitive electricaly transmission could in itself be a dominant factor in establishing

Paper 55-184, recommended by the AIEE System Engineering Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted July 15, 1954; made available for printing November 24, 1954.

H. D. Hunkins is with the Bureau of Reclamation, Denver, Colo.

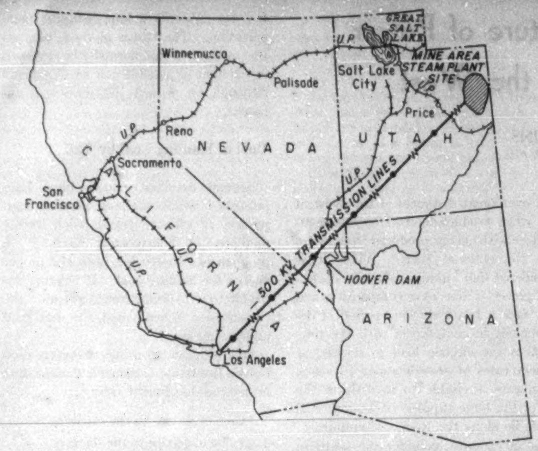

Fig. 1. Location of coal resources in eastern Utah, existing rail lines, and possible transmission-line routing to southern California

and regulating this rate. Freight rates are subject to increases as expenses of railroading increase.

Heiner, the author of an excellent paper on economics of coal for west-coast power generation assumed rail transportation as the cheapest method,[6] and felt that the export rate for hauling coal could be obtained for large movements. This rate now applies only to coal to be loaded into bunkers for water shipment and was $5.05 per ton in 1949, when the paper was written.

A rough approximation of the cost of shipping coal by rail may be made from the following 1952 rates from Price, Utah, to Los Angeles, Calif:

Slack coal, domestic rate, $6.70 per ton.
Size coal, domestic rate, $7.55 per ton.
Export rate, $5.39 per ton.

A determined rate of $5.15 per ton was used in this study and the transportation cost per kw-hour was computed to be about 2.19 mills for a coal having a heat content of 11,700 Btu per pound. The heat content of the coal in all parts of the mine area would have to be determined, as an increase or decrease in heat content would result in a corresponding change in rail transportation cost per unit of energy while electric transmission costs would remain more nearly constant. This figure includes the annual cost of step-up transformers from generator voltage to 230 kv for load-area distribution, for comparison with costs of electric transmission. The necessity of locating large new power plants away from heavily populated areas and for minimizing the number of trunk lines through and around load areas has already made the use of 230 kv economical for load-area trunk lines.

Fig. 2 shows the indexes for cost of construction of transmission lines and substations compared with the export freight rate from the Rocky Mountains to the west coast, using 1940 as the base year. By 1954 construction costs more than doubled while the export rate increased only 36 per cent (%).

Hauling 22,500,000 tons of coal annually by rail would require extensive new investment, as may be seen by the fact that in 1949 the railroads had only sufficient rolling stock to move approximately 2,000,000 tons of coal per year from Utah and Wyoming to the west coast.[6] A determination should be made as to whether extensive new railroad investment might require an increase in rail rates until the rail cost index were more in line with the construction cost index; i.e., approximately double the 1940 rate for hauling coal instead of increasing only 36%. If the 1940 rate of $4.26 per net ton were doubled, the cost of rail transport would be 3.57 mills per kw-hour on the same basis as the 2.19-mill cost estimate.

Rather than expand rail facilities to meet the full requirement, including northern California, which would under similar estimates require an additional 12,500,000 tons annually, it may be well to consider the merits of reducing this transportation load by means of electric transmission.

Qualifications of Electric Transmission

It must be assumed at the outset that an electric transmission scheme with mine-mouth plant, would have to meet certain basic requirements: first, it must meet economic competition offered by rail transportation of coal; second, it must be efficiently integrated technically and economically into the load-area power situation, beginning with the initial lines until a reasonable future time when changing economic or technical factors might change the trends in planning; third, it must provide reliability of service comparable with having the plants in the load areas and, in addition, yield side benefits in addition to strictly economic or technical advantages such as could arise from placing administrative control of the energy transportation facilities in the hands of the electrical utility.

Historically, long-distance transmission has been justified on the basis of transmitting bulk energy rather than as a means of obtaining peaking power at low-load factor. Tie lines between power systems built essentially for interchanging kw have usually been short, and built with a minimum of investment.

To meet the qualifications for bulk transmission, three principles of design are generally accepted. The first is to obtain high individual circuit loadings to work the tower steel which represents a major portion of the initial investment most efficiently. Limitations on this circuit loading are transient stability power limit and the cost of extra equipment, such

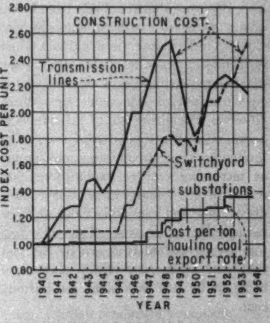

Fig. 2. Cost index for export freight rate compared with cost indexes for construction of transmission lines and substations

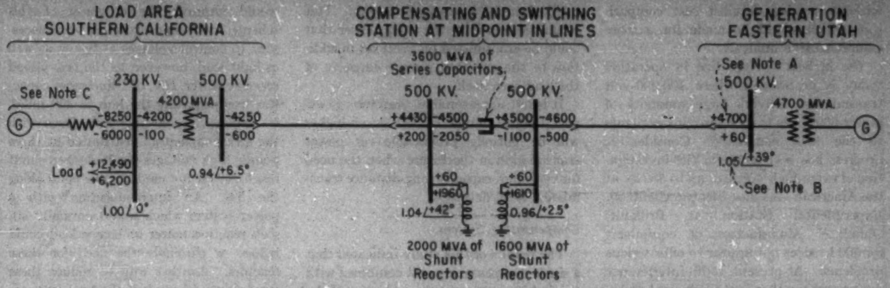

Fig. 3. Transmission of 4,200,000 kw at 500 kv over six lines 660 miles long, compensated to an equivalent length of 300 miles

A—Power shown in megawatts above the line and in megavars below the line. A positive sign indicates flow from a bus

B—Operating voltages shown in per unit of designated bus voltages. Angles given with bus voltages relative to 230-kv load area bus. The compensating station decreases over-all angle between sending station voltage and receiving station voltage

C—Receiving system represented by equivalent machine, impedance, and load. Synchronous condensers included in equivalent. Total equivalent load supplied by hydro and steam generation in load area and 500-kv transmission

as series capacitors and extra switching stations required to maintain transient stability at increased loadings. The second is to maintain a high transmission load factor in order to transmit the greatest amount of energy commensurate with the cost of stand-by capacity in the transmission system. The third is to minimize electrical losses commensurate with additional investment required in conductors and towers.

The problem then, like most engineering designs, becomes one of first determining the technical means, then balancing between the technical and economic factors. In this case, available solutions to the problems associated with long-distance transmission make such a project technically feasible. A number of papers on electric transmission show that the economic solution is approaching the point where electric transmission of bulk energy from mine-mouth plants may become less costly than hauling coal to load-area plants.[1–4]

Technical Features of Electric Transmission

A transmission system that might be considered typical on the basis of present-day technology was studied for transmitting up to 4,200,000 kw from eastern Utah, approximately a 600-mile air-line distance to Los Angeles, Calif. The total estimated load of 12,500,000 kw would be supplied principally from 3,100,000 kw of hydro capacity, 5,200,000 kw of steam capacity in the load area, and 4,200,000 kw of steam capacity at the mine. Only a-c transmission was considered. A more complete analysis of the problem should include d-c transmission.

To establish completely the practicability of such a large electric transmission system, extensive engineering and economic studies would have to be made. Studies made for this paper were of an exploratory nature to determine the present competitive position of electric transmission with respect to rail-hauling of coal in the Far West.

DESCRIPTION

Fig. 3 shows a schematic layout of the plan studied with power flow and voltages. For purposes of discussion, this scheme is divided into four components: The sending-end system, transmission lines, the compensating system, and the receiving-end system.

Sending-End System

The sending system might consist of several large power plants of from 1,500,000 to 2,000,000 kw each, located at advantageous points in the mine area, with step-up transformers connected to lines at transmission voltage. These would connect the plants to a centrally located switching station which would be the starting point of the transmission system to the coast.

The generators and prime movers, it is expected, would be the largest and most efficient available, of around 300,000 kw, with heat rate down to 9,600 Btu's per kw-hour or less, based on present-day designs. Extra units would be installed to allow for a maintenance schedule. For this study, actual cost of production within the plant was assumed to be the same whether the plant was located in a load area or at the mine.

The basis used in estimating the number of circuit breakers required at the switching stations to allow for tie breakers and spares approximating present design practice was $1^1/_2$ times (line breakers plus transformer breakers). The interrupting duty of high-speed sending-end breakers might reach 30,000,000 to 40,000,000 kva. The industry has built circuit breakers capable of interrupting 25,000,000 kva at 330 kv, and there is no indication that the limit has been reached.[7]

Transmission Lines

For transmitting 4,200,000 kw, six 500-kv transmission lines were assumed with busses at the sending end, mid-point, and receiving end. For cost estimates, single-circuit steel tower construction was assumed based on light loading. Line mileage was taken as 110% of the point-to-point distance measured from a map to allow for variations in the routing. A duplex arrangement using two steel-reinforced aluminum-cable conductors of 1,590,000 circular mils per phase was used. Detailed studies might show that a bundle arrangement having more conductors per phase and a larger total size would be more economical. The use of bundle conductors overcomes the problem of corona[8] and reduces the series compensation required, while larger conductors reduce the energy loss.

The choice of voltage would be affected by a number of factors, such as distance, magnitude of load, number of interconnecting stations, and technical and economic feasibility. Considering the distance and magnitude of load in this study, a voltage in the extra-high-voltage range was indicated, and 500 kv was selected without making detailed cost comparisons which would be made for a more comprehensive analysis.

The highest voltage line in operation today is in Sweden where 400,000-volt transmission delivers large amounts of power 600 miles from hydro power plants to the load centers.[9,10] Considerable progress has been made in the investigation of extra-high voltages up to 500 kv at the American Gas and Electric Company Experimental Station at Brilliant, Ohio.[11-17] Manufacture of equipment for 500 kv does not appear to offer serious problems. At present, radio interference during wet weather is the principal objection, but this difficulty may be overcome by the time the application foreseen in this paper occurs.

For distances greater than about 350 miles, as in the case of these studies which require transmission of power a distance of 660 miles, it has been determined that the surge-impedance loading represents a practical limit on the maximum power that should be transmitted per line.[8] A voltage of 500 kv provides a surge-impedance loading of about 625,000 kw for a single-conductor line. A duplex-conductor arrangement increases this to about 750,000 kw per line.

An annual growth of 5% of the total 1975 load would be 625,000 kw. For the purposes of this study and on the basis of present expansion of steam-power generating facilities in the load area, about one-half of this might be expected to be supplied by local plants and the other half from the remote plant located at the mines in eastern Utah. On this basis, a new line would meet the load-area needs for about $2^{1}/_{2}$ years, and the loss of a line section would not seriously limit the ability of the system to meet peak loads. In the event that one complete circuit were lost, it would represent only about 5.5% of the 1975 area load on peak. This would be less than the extra power that could be transmitted on overload in addition to the expected reserve capacity of the load area itself.

It is not unreasonable, therefore, to expect that a voltage of 500 kv or higher will be entirely practicable for power transmission in the future when the need for very high-capacity long-distance transmission lines develops.

Compensating System

The results of this study indicated that a single compensating unit combined with a switching station at the mid-point of the six transmission lines would provide an economic transient power limit and complete voltage control from no load to full load.

The compensating unit shown in Fig. 2 consisted of a series capacitor with shunt reactors on either side to form a pi-type circuit comparable to the equivalent pi-circuit for a transmission line used in network analyzer studies except with the capacitor in series and inductive reactance in shunt. This, in effect, reduced the length of the line from its physical length of 660 miles to an electrical length of 300 miles. The constants were selected to provide a surge-impedance loading close to that of the line itself. Making the shunt reactor on the output end of the series capacitor larger (with lower admittance) than the one on the input side provided an increase in transmission voltage at the compensating station. The amount of compensation could be expressed as 50% of the nominal line reactance, 69% of the imaginary component of the *B* constant, or 55% of the line mileage.

The design of the compensating system was not refined to determine whether reducing the size of the shunt reactors would improve the economy of this scheme. The shunt reactors were necessary to control voltages at heavy as well as light load, however, as the heavy-load reactive power, I^2X, of 1-line series capacitor, compensating the line to 300 miles, was about 525,000 kilovars. Even with the series capacitors distributed at three points, high voltages resulted when shunt reactors were not used at some point along the line. An interconnection with a power system which would normally absorb reactive power at heavy load could reduce or eliminate the need for these reactors. Another way to reduce these reactors would result if the transient stability power limit were high enough to permit operation well above the surge-impedance loading of the line. It was also noted that use of conductors having a higher resistance-reactance ratio, in the order of 0.10, reduced the need for the shunt reactor as the resistive component of voltage drop at heavy load tended to overcome the voltage rise at the center of the line created by flow of reactive power toward the sending end of the line. However, the high losses resulting from the use of such high-resistance conductors would not be economical. Reactive capacity would probably have to be added at the receiving end to support the voltage, and underexcited machine operation might have to be accepted at the sending station if the purchase of shunt reactors were to be avoided.

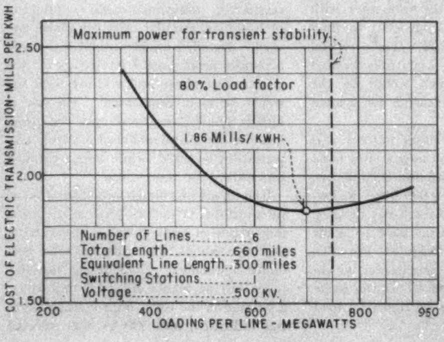

Fig. 4. Determination of economic loading

Studies were made for compensating the 660-mile line to equivalent lengths of 100, 200, 300, and 400 miles. Compensation to 300 miles provided a transient stability limit of about 750,000 kw per line for six lines in parallel and appeared to be near the economic point in amount of compensation.

The studies indicated that one intermediate switching station would be adequate after three or more lines are built in parallel. The initial system would require three switching stations, two of which could be eliminated and the equipment used at the centrally located switching station as more lines were built.

Receiving-End System

The long transmission lines would terminate at a receiving switching station where the voltage might be stepped down to 230 kv for subtransmission in the load area or the extra-high voltage lines extended to other step-down points in the area. The load kilovars would be provided as close to the load as possible by synchronous condenser or static capacitors. The transmission lines did not require kilovar support at full load.

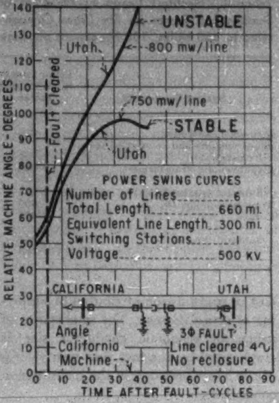

Fig. 5 (left). Power-swing curves

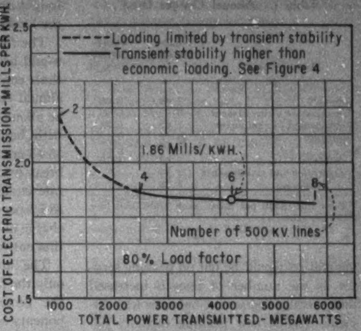

Fig. 6 (right). Effect of total load and number of lines on cost

LINE LOADING AND TRANSIENT STABILITY

Studies of economic line loading and transient stability were made to develop a workable and economical system. The first general approach was to compensate the line reactance until the voltage angle from sending to receiving end was about 30 degrees, which would occur for an equivalent length of about 300 miles. Experience has shown that several lines in parallel will usually maintain transient stability for severe faults up to about 30 degrees between the sending- and receiving-end voltages.

Economic Line Loading

The receiving-end load on this system was then varied in steps from about 350,000 to 900,000 kw per line. For each increase in power, there was a corresponding increase in the kva rating required for terminal transformers and series capacitors at the compensating station as well as an increase in the line losses. Although the amount of series compensation remained the same in ohms or equivalent length, the kva rating of the capacitors increased with the square of the current. The annual cost of equipment plus losses was computed for each loading and divided by the kw-hours that would be delivered in a year, assuming the average line loading at 80% of capacity. This gave the costs of transmission in mills per kw-hour, which are plotted in Fig. 4. The minimum cost occurred for a loading of 700,000 kw per line.

Several of these curves were obtained in the course of the study with the use of different amounts of line compensation. Compensation to an equivalent length of 300 miles was selected because the economic line loading shown in Fig. 4 was found to be close to the minimum cost of transmitting energy. Compensating the line to an equivalent length of 200 miles increased both the level of the cost curve and the distance between the minimum cost point and the transient stability limit. Studies also indicated that reduction in compensation toward an equivalent length of 400 miles might reduce the level of the cost curve a small amount, but would probably reduce the stability limit to the point that a seventh circuit would be required to transmit 4,200 megawatts.

Transient Stability

After the curves of economic loading were obtained for normal power flow, transient stability studies were made to determine the amount of power that could be carried through severe disturbances such as short circuits on one high-voltage line. The power limit for six lines was found to be 750,000 kw per line, which was in excess of the economic loading shown by Fig. 4. In view of the most economic loading and to have some margin below the 750,000-kw stability limit, the loading of 700,000 kw was considered to be a reasonable loading for the cost analysis.

Transient stability limits on power transfer were also determined for other than six lines. In each case, the relationship of economic loading and transient stability determined the maximum load and amount of compensation to be used in estimating costs. One switching station was used for the 6-line case, and as many as three switching stations were required for the 2-line case which would probably represent the initial system. In the case of six lines, three switching stations were not required. The cost of the two additional switching stations with the six lines increased the level of the economic curve and did not appreciably increase the power limit.

Future studies of this problem should consider means of increasing the transient stability power limit for less than four lines. Switching out a portion of the shunt reactors at the compensating station during the critical period of the swing would reduce excitation requirements of the transmission system and increase the height of its steady-state power-angle curve. The series capacitors could also be rearranged by high-speed switching to provide increased compensation during the swing.[18]

To be conservative, 3-phase faults were assumed near the 500-kv sending bus with 4-cycle clearing of the faulted line and no reclosing. Fig. 5 shows a typical set of swing curves in which the practical power limit was determined for the 6-line transmission system which was 660 miles long and compensated to an equivalent line length of 300 miles with one switching station at the mid-point.

Economic Features of Electric Transmission

The economics of electric transmission from remote mines may be divided into two parts. The first is associated with the broader planning and the second directly involved in the design and operation of the lines. Emphasis is placed on the influence of the various cost factors.

BROAD PLANNING

Proper planning of the division of generation between the load area and the mine would be expected to make a smooth transition from all generation in the load area to production of a large portion of the base-load energy at the mines. An increasing proportion of the load-area

Table I. Annual Charges Used

Annual Charge	Sub-stations, %	Trans-mission Lines, %
Interest	3.00	3.00
Amortization of investment	0.89	0.89
Replacement of equipment	1.62	0.74
Insurance	0.12	0.12
Subtotal	5.63	4.75
Operation and maintenance	2.15	*
Total	7.78	

* First line, $320 per mile; each additional line, $107 per mile.

generation would be put on peaking service as the number of lines is increased and existing equipment becomes less efficient. When new peaking capacity becomes necessary in the load area, costs might be reduced by designing specifically for low-load factor operation just as in the mine area special emphasis would be placed on high-load factor operation. Considerable study would have to be made along these lines in establishing the feasibility of such a scheme.

Fig. 6 shows that transmission costs would be higher during the initial stages of the project when fewer lines are in operation. The dashed portion of the curve up to four transmission lines in parallel represents maximum line-loading as limited by transient stability. It is believed that the stability limits on maximum power transfer in this range could be increased with resulting decreases in annual cost by methods discussed under transient stability.

Design and Operation

The economic factors directly involved in the design and operation of the lines are: 1. the annual charges, 2. the cost of electrical losses, 3. the economic loading and transmission-load factor, and 4. the initial costs of construction.

Annual Charges

The annual charges used in this study included interest, amortization of the investment, replacement of equipment, insurance, and operation and maintenance as shown in Table I. When expressed in percentages and multiplied by the respective construction costs, the annual fixed expenses over the life of the project are obtained. Operation and maintenance is often expressed on a unit cost in dollars per mile of line or per kva of station capacity.

With the use of these annual charges and a transmission load factor of 80%, the cost of electrical transmission was computed to be 1.86 mills per kw-hour. The estimated cost by hauling coal at a freight rate of $5.15 per ton, 2.19 mills per kw-hour, would be 18% higher.

The feasibility of electric transmission would bear heavily on the annual charge that could be obtained. The over-all annual charge used for this study would be about 6.5%, and the break-even point with hauling coal at a freight rate of $5.15 per ton would be about 7.6%. The break-even point for hauling coal at a rate equal to twice the 1940 export rate, $8.52 per ton, would occur for an annual charge of about 14.6% with a transportation cost of about 3.57 mills per kw-hour.

The annual charge used affects not only the feasibility of the project but also the economic design of system components as indicated in the recent paper on the Ohio Valley Electric Corporation (OVEC) project.[19] It was pointed out that for annual charges of less than 8%, normally accepted economic relationships to design can be altered. For a lower annual charge, greater initial investment can usually be justified, such as for larger conductors, to attain higher transmission efficiency. These factors emphasize the importance of thoroughly investigating the economic situation before the engineer can begin his work.

Cost of Electrical Losses

Table II shows the electrical losses in per cent for components of the system studied. The over-all efficiency of the transmission system was computed to be about 89.8% with 27.5% of the annual cost of transmission attributed to supplying electrical losses. The importance of using an economic conductor size is emphasized by the fact that nearly 69% of the losses occurred in the transmission conductors.

Table II. Electrical Losses in Per Cent of Sending-End Power for Six Lines Compensated to 300 Miles, 700 Megawatts per Line

System Component	Power Loss in % of Sending Power
Step-up transformers	1.002
Shunt reactors and connecting transformers	1.244
Step-down autotransformers	0.688
Subtotal (station losses)	2.934
Transmission line I^2r	7.000
Corona	0.254
Subtotal (line losses)	7.254
Total	10.188

The annual cost of generating equipment plus fuel costs were included in determining the cost of losses. For estimating the effect of increased annual charges on the cost of transmission, the cost of losses was increased accordingly.

Maximum Economic Line-Loading and Transmission-Load Factor

The maximum economic line-loading and highest annual transmission-load factor on the lines yields the lowest cost per kw-hour of energy delivered.

Economic line-loading for six lines has been discussed, and it was found that the

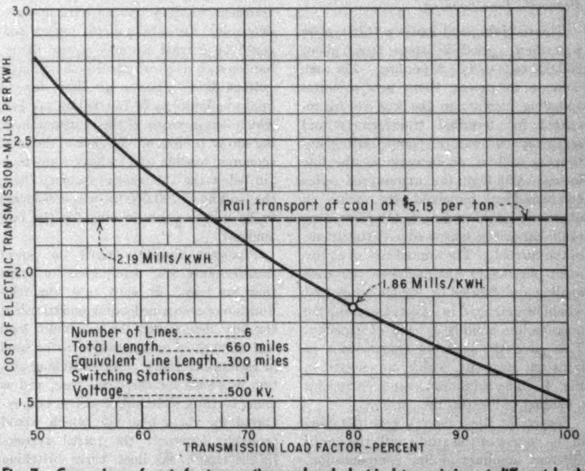

Fig. 7. Comparison of costs for transporting coal and electrical transmission at different load factors

minimum cost of transmitting energy occurred for a receiving power of 700 megawatts per line with a safe margin in transient stability. For the initial two lines that might be built, the cost of transmitting energy would be greater, as shown on Fig. 6, because of the limiting factor of transient stability on the power that can be transmitted economically. The effect of increased costs in the initial system would have to be investigated to determine whether it could be absorbed in anticipation of savings as the number of lines increases. In this respect, the timetable of installation of new lines becomes important.

Fig. 7 shows the effect of transmission-load factor on the cost of electrical transmission. An increase in load factor from 80 to 90% would decrease the cost of transmission to about 1.66 mills per kw-hour, or approximately 10.7%, based on the annual charges used in this study.

INITIAL CONSTRUCTION COSTS

In the following are listed the initial costs of construction (1952 estimates) used in this study. The increases in these costs since 1940 in relation to the increases in the cost of hauling coal were discussed under the section on cost of hauling coal by rail.

Transmission line (single circuit, including right of way and clearing), $73,370.00 per mile.

Step-up transformers, 11.10 per kva.

Step-down transformers for shunt reactors, 11.10 per kva.

Autotransformer 500–230 kv, 15.60 per kva.

Circuit breaker and bay, 420,000.00 each.

Lightning arresters, 7,500.00 per position.

Series capacitors, 27.60 per kva.

Shunt reactors, 7.20 per kva.

Synchronous condensers, 11.40 per kva.

Table III gives the percentage of total initial cost for each of the major types of equipment in the transmission system in terms of the initial construction cost. The transmission line and station costs were each near 50%. The higher annual charge for station equipment, however, made the cost of stations approximately 45.5% of the annual cost of transmitting energy with 27% for transmission lines and 27.5% for electrical losses.

Conclusions

1. On the basis of these comparisons, it appears desirable that continuing study be made on the feasibility of electric transmission as compared with other means of moving energy stored in Rocky Mountain coal over long distances between the mines and major western load areas.

Table III. Initial Cost of Equipment and Lines in Per Cent of Total Cost for Six Lines, 300-Mile Compensation

Type of Equipment	Costs in % of Total Cost
Terminal transformers	19.52
Circuit breakers	4.54
Series capacitors	14.25
Shunt reactors with step-down transformers	10.59
Lightning arresters	0.03
Synchronous condenser at receiving end	3.47
Subtotal for stations	52.40
Subtotal for lines	47.60
Total	100.00

As a result of increasing cost of exploration for oil and natural gas, estimated future demand in relation to new discoveries, and increasing value of these resources for other uses, coal may become a major source of electric energy to meet increasing loads prior to economic production by other means such as atomic and solar energy or tide and wind action.

2. The existence, or apparent feasibility, of electric transmission as a competitor with rail-hauling of coal could become a factor in determining and regulating coal freight rates.

3. Considering that extensive new railroad investment might be required to meet future requirements for hauling coal, careful investigation into the future of freight rates between Utah and southern California would be warranted.

4. On the basis of the very large physical increase in railroad facilities that might be required, principally for hauling coal, reducing this requirement by using electric transmission becomes an important consideration.

5. Electric transmission over 660 miles is apparently within present-day technology. Development of new equipment for maintaining control near abnormally large concentrations of generation during system disturbances and for operating in the extra-high-voltage range, above present usage, appears possible.

6. The practical limit on transmission-line loading over long distances appears to be restricted by transient stability for the first few lines built in parallel and then principally by the annual cost of equipment plus losses.

7. On very long lines requiring series capacitor compensation and without intermediate load points, shunt reactor compensation may be necessary to limit voltage rise even at heavy load.

8. After several parallel lines have been built for long-distance transmission, satisfactory stability performance appears possible with only one intermediate station containing both the compensating and intermediate switching equipment.

9. The influence of annual charges on the cost of electric transmission indicates that detailed investigations should be made on the economic factors involved.

Discussion

M. S. Oldacre (Stanford Research Institute, Stanford, Calif.): The change in the energy supply of the West and the probability that coal will become an important factor in an area now dependent on water power, petroleum, and natural gas is the most important point of the paper, even though little is presented on the relative cost and availability of various fuels and other data that must be known before effective comparison can be made of the cost transporting different forms of energy.

Papers on the economic energy source for an area are usually fairly thorough analyses of only one phase of the problem, with data for making comparisons of methods for delivering energy abstracted from other papers. The author goes beyond the usual presentation, in outlining the factors to be considered in a complete analysis, and then considering in detail the technical question in high-capacity electric transmission. It seems safe to assume that electric facilities can be provided for any reasonable extension beyond present capacity and distance of transmission and that therefore more attention should be paid to the economic factors.

All this suggests the need for a comprehensive analysis of the whole problem, and that the AIEE should take an active part in the studies of the economics of energy supply to an area. Initially, individual members or the technical committees could study various parts of the problem and co-ordinate their activities to secure a comparative analysis. The industry should sponsor a research project that could be carried on a continuing basis to obtain comparative data on the cost of energy supply to the different load centers when used in the various sources, and also to show which sources are best used for lowest over-all cost. The question of energy supply in the future is a vital one.

C. W. Watchorn (Pennsylvania Water and Power Company, Baltimore, Md.): The paper is a most inspiring one. A bold look to the future is the way to achieve real progress. It is realized that this report is a preliminary survey of uncertain future possibilities, but a few factors come to mind which perhaps should be given fuller consideration.

First, comparable reliability is doubtful with each of the author's two alternatives (see references 1 and 2 of this discussion). In the problem of maintaining comparable reliability, whether the economical solution is obtained by: 1. providing additional transmission facilities to the load area, or 2. providing additional generating capacity in the load area, over that proposed in the paper, with the mouth-of-mine steam-generating plants or by other means, the result is the same: investment costs are higher than they would be on the basis considered in the paper. Depending on the results of such an evaluation, the mouth-of-mine generation may prove much less attractive than it appears on the basis of the evaluation in the paper, where this factor may not have been evaluated.

A demonstration of the justification for the high-load factor as assumed in the paper in the evaluation of the costs of electric energy transmission with the mouth-of-mine plants would be most interesting, since this factor is of primary importance in such an evaluation.

In considering the economics of annual carrying-charge rates, the following comments are not intended to be against the public interest but rather they are intended to be in the best public interest, in advocating observance of economic laws, the violation of which can never be in the public interest, since economics is a natural force that will exact its own penalties in one way or another if its laws are violated.

Usually, the problem is presented as that of determining the relative economics of transporting energy on the one hand in the form of fuel over already existing facilities and on the other hand as electric energy over facilities that must be built; whereas, in the paper the problem is that of determining the relative economics of transporting energy over facilities not only required to be built for electric energy transmission but also largely required to be built for the transportation of energy as fuel. The differences, however, are in the details and not in the fundamentals. Charges for fuel transportation for the usual case are properly based on filed tariffs or on whatever other arrangements may be made with the transportation companies. However, the author's case is not so clear-cut in this regard, without a definite proposal for arrangements as to transportation charges for the fuel. In the absence of such a proposal, consideration should be given to what the possible freight rates or transportation charges might be.

This would be a complicated process. Nevertheless, since for the author's conditions, existing transportation facilities can move but a small portion of the total fuel required, and additional facilities are needed to move the major portion, it may be assumed that the transportation charges would be based largely on the actual costs of providing such services, i.e., the annual carrying charges, operating, and maintenance costs of such new facilities.

Upon what basis, then, private or so-called government financing, should the annual carrying charges be determined? It appears from the paper that basically the fuel transportation charges are predicted on private financing and the electric energy transmission costs on government financing. However, it is just as logical to reverse the assumptions, and base the fuel transportation charges on government financing and the electric energy transmission costs on private financing, in which case an indication is conceivable of more economy in transporting fuel than in transmitting electric energy rather than the reverse as suggested in the paper. Obviously, such conflicting results are untenable. One of the alternatives must be the more economical, independent of the assumptions. The basis for the calculations must be compatible with the facts to be determined, i.e., the question should be decided as to which alternative is really the more economical, rather than the results allowed to be a by-product of the assumptions.

A partial solution is to assume the fuel transportation and the electric energy transmission both on the same basis of either private or government financing. With such an assumption it is possible but far less likely that the fuel transportation would be indicated as the more economical with one basis of financing and the transmission of electric energy with the other than with different bases of financing, as is assumed in the paper and then as considered in the foregoing.

It is obvious that in all cases government financing results in apparently lower costs than private financing for the same job, particularly with high investment costs. This raises the question as to what magic there is in government financing and, as to why it is not used for every undertaking, thus raising all our standards of living because of the resulting lower prices. Actually, there is no magic in government financing, since the true costs or carrying charges are the same as in private financing. In government financing an allowance is usually made for interest only, the taxpayer thereby assuming the equity risk. Further, the tax provision in the allowance for carrying charges is grossly inadequate.

To continue the analysis, we may assume no public debt and all government financing on a pay-as-you-go basis, for which there would be no interest charges. Would the cost of money for government-financed projects then be zero? The answer, of course, is that it would not. The only rational evaluation is at the rate placed on it in the market place for undertakings of similar risks where it is voluntarily available from those whose money it really is in the first place, the general public's or the taxpayers'. The fact that the government may raise some of its money by borrowing cannot change this consideration in the slightest. Certainly, money made available involuntarily by way of taxes for a given project costs at least as much as that made available voluntarily by way of investments for the same project with equally competent management in both cases.

Next should be considered the treatment of taxes in the determination of the carrying charges. The noninclusion of an allowance for taxes with respect to government financing does not result in a reduction in the true cost of the project as an alternative. Rather it merely shifts the burden to the taxpayers and this cost item is carried by them when they pay their tax bills. Or, to say the same thing another way, the nonpayment or noncharging of taxes results in no over-all economic benefit to the public generally.

Thus, the relative economics of alternative projects are correctly determinable only on the basis of private financing in a free market. Whether or not the government is to finance the project, or whether rates charged for the services provided are higher or lower than if based on actual costs, are matters of public policy and are not proper considerations in the determination of the relative economics of alternative facilities (see reference 3 of this discussion).

Paul H. Jeynes (Public Service Electric and Gas Company, Newark, N. J.): The paper is an excellent long-range appraisal of an interesting situation. It contains one serious weak point, which apparently is realized by its author, concerning the details of the economic comparison.

The author states that the annual charge used affects not only the feasibility of the project but also the economic design of system components as indicated in the recent paper on the OVEC project (see reference 19 of the paper), and, in conclusion 9: "The influence of annual charges on the cost of electric transmission indicates that detailed investigations should be made on the economic factors involved."

This discussion undertakes to supply the results of such detailed investigations of annual charges. The author lists annual charges as: interest, amortization of investment, replacement of equipment, insurance, and operation and maintenance.

It is not clear why both amortization of investment and replacement of equipment should be included. The investment in the initial facilities results in annual charges for return on that investment, plus depreciation expense for those initial facilities during their lifetime. When they are replaced, the capital money invested in the replacement results in annual charges for return on that capital money, plus depreciation expense for the replacement facilities, during the lifetime of the replacement facilities. But during the lifetime of facilities currently in use there is never an annual charge for future replacements; annual costs of future replacements do not begin until the replacements are made, i.e., when they are actually "used and useful."

Nor is it clear why taxes are not mentioned. Utilities encounter a variety of taxes, all of which have to be recovered in revenues. Besides federal income tax there are usually real estate, franchise, and the so-called payroll taxes; in addition there are often state income taxes, personal property taxes (sometimes applied to gross receipts in lieu of property), and sales taxes or other levies on gross receipts.

The estimate of interest at 3% is not unreasonable, but interest ordinarily constitutes only about 25% of the total return that must be earned on a project of this kind. That is, a return of about 6% may be reasonably anticipated, although somewhat more might be required to induce investors to commit their capital to this apparently risky venture. About 50% of that capital probably would be raised by means of bonds, at about 3% interest. That accounts for 0.03×0.50=$1.50 of the $6 annual return per $100 invested. The other 4.50% would represent return on equity, which is subject to income tax. Federal income taxes, at current rates, would approximate 3.97% of the gross investment.

The author's estimate of amortization of investment at 0.89% apparently is based on a 50-year life, no-salvage value, no dispersion of retirements, and reserves reinvested in the enterprise at 3%. Accepting the 50-year life estimate, assuming zero net salvage, and assuming reinvestment in the enterprise at 6% (as just discussed), the depreciation annuity would be 0.34%, i.e., if no dispersion of retirements is assumed, all property units retired exactly at age 50, none earlier and none later. However, if the more reasonable assumption is made of 50-year average life, some items having shorter and some longer lives, that figure would be increased substantially. For a typical survivor curve like the Iowa type S_0, and assuming reinvestment at 6%, the annual cost of depreciation would be 0.86%, or practically the same as suggested by the author.

Accordingly, a minimum estimate of annual costs would seem to be as follows (for substations, and similarly for transmission lines)

Return	6.00%
Depreciation	0.89%
Income Tax	3.97%
Insurance	0.12%
Operation and maintenance	2.15%
Total	13.13%

as compared with the author's 7.78%.

Utility economists frequently arrive at a figure in the neighborhood of 15% for this purpose, about double the figure suggested by the author. Of course, such a rate changes the picture entirely.

There is one conclusion that is definitely proved by the author's figures, although I am sure that this was not his intent. If we assume government financing at 3%, with no taxes, we certainly could put the competing railroads out of business, unless, of course, we also socialize the railroads, finance them at 3% interest and omit taxes. On that same basis we can also take over the steel industry, the petroleum industry, the automobile industry, or any other capitalistic enterprise intent on earning a reasonable return for its owners, and subject to taxes on that income. Comparisons on that basis are occasionally made, with the pretense that they are "economic" comparisons.

W. R. Johnson (Pacific Gas and Electric Company, San Francisco, Calif.): This is an interesting academic study of future power needs in the West. The technical assumptions upon which the transmission scheme is based are substantially an extrapolation of present developments in this country and abroad.

The author refers to the OVEC financing with total annual charges for interest, taxes, insurance and amortization to run less than 8%. The OVEC has a long-term government contract for sale of power to the Atomic Energy Commission at a high annual load factor and has consequently been able to obtain financing at a low cost. It seems unlikely that equally favorable conditions for low-cost financing can be assumed for the Utah-California transmission discussed in this paper. In spite of this, in Table I the author uses annual charges of only 5.63% for substations and 4.75% for lines, excluding operation and maintenance which are likewise not included in the OVEC 8% figure. It is evident this economic analysis is based upon the use of public credit to obtain low interest rates, and of a tax subsidy in addition by the total omission of tax costs. How can such costs properly be compared with railroad freight rates which reflect both the cost of taxes and of private financing?

Failure to compare costs on a comparable basis may result in the misallocation of resources and the use of less economical alternatives. A theoretical engineering study such as this should be completely objective in both its technical and economic approach to the problems under consideration if it is to be a real contribution to electrical engineering.

The inclusion of more representative annual charges would increase the transmission costs as shown in Fig. 7 on the order of 75%. Instead of 1.86 mills per kw-hour, as indicated for 80% load factor, a figure of 3.2 mills would be more appropriate.

In conclusions 3 and 4 the author indicates that "...extensive new railroad investment might be required to meet future requirements for hauling coal..." and that "On the basis of the very large physical increase in railroad facilities that might be required, principally for hauling coal, reducing this requirement by using electrical transmission becomes an important consideration." The implications of these two conclusions are unwarranted. The concentrated delivery of large volumes of coal to a few terminal points is well suited to railroad haulage; it would develop gradually and would not require extremely large or sudden increases in railroad facilities or investment.

Finally, it should be pointed out that the informed opinion of today is that within 20 years 10 to 15% of the electric power generation will be from atomic plants, and that in the last quarter of this century most new generating capacity will be from such plants. Estimates of fuel costs for these plants are well under even the transmission cost alone as indicated by the author. Atomic plants of this character would operate on base load, leaving the hydro and higher fuel cost plants for peaking operation. Such development would tend to make economically obsolete the mouth-of-mine, coal-fueled plants with very long transmission distances.

H. D. Hunkins: The author appreciates the discussions and finds substantial basis for agreement with many of the points discussed, among them, the suggestion by Mr. Oldacre that the AIEE should take an active part in the studies of the economics of energy supply. Such a penetrating analysis should, through research, bring out new techniques in the handling of coal fuels and methods of transporting energy. It should, through the democratic process of free discussion, result in a maximum working of the economic law ably discussed by Mr. Watchorn.

In first considering the preparation of the paper, it was clear to the author that the annual charges used in the original study made in 1952 were near a minimum. It was also noted that the relationship between the freight rate index for hauling coal from Utah to the west coast and the index of construction cost for the year 1952 were very much out of line with that prevailing in 1940 as illustrated by Fig. 2.

Since coal freight rates are regulated by a commission, and the railroads have been continuously applying for rate increases, it appears likely that with increased demands on the railroads for hauling coal, an adjustment would occur tending to restore balance between the indexes of construction costs and freight rates existing in 1940. The paper in one sense compares cost figures based on a low annual charge with a freight rate that is also considered low, and extrapolates these figures for comparing higher annual charges with higher freight rates.

In reply to Mr. Jeynes, replacement of equipment was included in the annual charges because in financing a project consisting of many major components over a relatively long period, it is recognized that all components will not have the same life span or a life span necessarily corresponding with the life of the project. The amount charged annually during the life of the project for replacement of equipment in this case is over the cost of operation and maintenance and is expected to replace partially or completely those components whose life span is less than the life of the project. It is noted that the replacement item for substations was 1.62%, while for transmission lines it was 0.74%. Some believe that a properly constructed steel tower line would have a life expectancy of 50 years which would decrease the replacement item for lines to zero in this case.

At another point Mr. Jeynes includes the replacement of equipment item as defined in the previous paragraph, plus amortization of investment in one term, depreciation, and obtains a figure considerably lower than the sum of the two items shown in the paper. It is believed that this results from the fact that the method used for computing annual charges in this paper does not permit reinvestment of funds accruing from depreciation allowance or amortization of investment. Mr. Jeynes states that his figure is based on such reinvestment.

Mr. Johnson's references to the time that electrical production from atomic fuels may be available, at a very reasonable cost, is encouraging from the standpoint of supplying future loads. Are there, however, sufficient assurances today of this future supply to warrant abandonment of investigations into the use of coal in the West? Does the philosophy that railroad growth is slow greatly improve the position of rail hauling? And can it be said without further study that mouth-of-mine plants and transmission lines would become obsolete before the end of their useful life?

An Investigation of the Economic Size of Steam-Electric Generating Units

L. K. KIRCHMAYER

A. G. MELLOR
MEMBER AIEE

J. F. O'MARA
ASSOCIATE MEMBER AIEE

J. R. STEVENSON
ASSOCIATE MEMBER AIEE

THIS paper records the method of analysis and the results obtained of a study made to determine the optimum economic size of steam-electric generating units that should be added to a power system. Factors such as the size of system, forced outage rate, rate of load growth, installed cost of larger generating units, the effect of a maintenance program, and the effect on the transmission system of the use of larger generating units have been taken into account. The practicability of designing and building very large generating units has not been considered in this paper as it is thought that if such large units can be economically justified the equipment manufacturers will find means of developing them.

Studies of this type based on probability methods involve an extremely large number of numerical calculations and would not be practical without the aid of automatic digital computers. It is hoped that the procedure given in this paper will provide utility engineers with a tool for determining an optimum plan for generating station additions to an individual system.

Conclusions

Based on the assumptions made in this study, the following trends may be noted from the results presented:

1. If the investment cost of large units continues to decrease with size and the forced outage rate for large units remains at the present level [2 per cent (%) or lower], the most economical pattern of system expansion is to add units of between 10% and 7% of the size of the system studied. The slope of the curve of cost per kilowatt (kw) versus size is the determining factor rather than the absolute values of investment cost.
2. If above any size the investment cost in dollars per kw remains constant, there will be very little incentive to use units above this size.
3. Any increase in the forced outage rate of large units will slow up the move to these large units.
4. For the range of rates of load growth normally encountered, the rate of load growth of a system has no appreciable effect on the size of units that can be economically justified on a system.
5. Due to the decreasing gain in investment cost and operating costs as unit sizes increase, units that are a larger percentage of system size can be justified more easily on smaller systems than on large systems.
6. Due to the decreasing gains from larger units, it appears that the rate of increase of the maximum size of units may slow down, but there is no indication that the maximum economic size of units has been reached yet.
7. Based on the factors considered in this study, it can be conservatively estimated that unit sizes of the order of 500 to 600 megawatts (mw) will be economically utilized on some power systems within the next 10 years.

System Studied

In this study a basic existing system of 2,000 mw total generating capability was assumed, consisting of 12 25-mw units, 20 50-mw units, and 7 100-mw units. All units making up the basic system and all units added to the system were assumed to be of the unit scheme type, i.e., single boiler, turbine-generator set. It was assumed that the transmission system was adequately designed to carry the full output of the generating stations to the load areas.

Expansion of the system was carried out from the basic system of 2,000 mw to a system of approximately 10,000 mw. In this expansion four basic patterns were investigated:

1. 8% to 5% expansion. The size of units was kept within a band of 8% to 5% of the total installed capacity of the system. This means, e.g., that for the basic system of 2,000 mw the first unit added to the system would be 8% of 2,000 mw or a 160-mw unit. This size of unit would be added every time new generation was required, until the unit

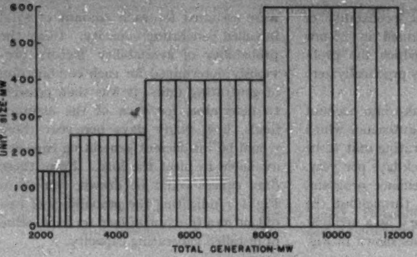

Fig. 1. Unit size as function of total generation with 8% to 5% expansion

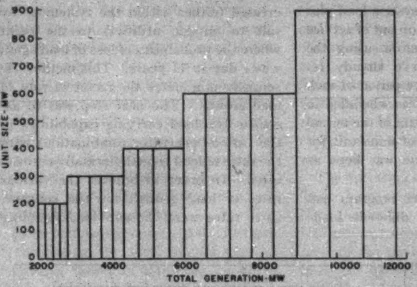

Fig. 2. Unit size as function of total generation with 10% to 7% expansion

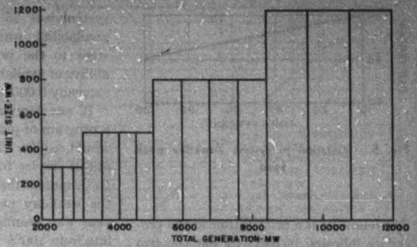

Fig. 3. Unit size as function of total generation with 15% to 10% expansion

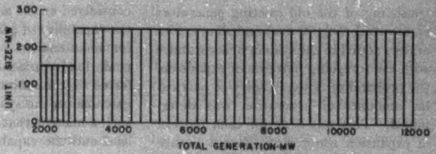

Fig. 4 (above). Unit size as function of total generation with 250-mw expansion

size was approximately 5% of the total system generation or, in this case, until the system generation totaled 3,200 mw. When this point was reached, the next unit added would be 8% of 3,200 mw or approximately 250 mw.

2. 10% to 7% expansion. The size of units added was kept within a band of 10% to 7% of the total capability of the system.

3. 15% to 10% expansion. The size of units added was kept within a band of 15% to 10% of the total capability of the system.

4. 250-mw expansion. The size of units added was initially kept within a band of 8% to 5% of the total installed capacity of the system up to units of 250-mw capacity, after which the system expansion was continued with 250-mw units regardless of system size.

To simplify the calculations, the unit sizes actually used were not exactly in accordance with the percentage bands just indicated. The sizes used were as follows and are shown in Figs. 1–4.

1. For 8% to 5% expansion, the unit sizes were 150, 250, 400, and 600 mw.

2. For 10% to 7% expansion, the unit sizes were 200, 300, 400, 600, and 900 mw.

3. For 15% to 10% expansion, the unit sizes were 300, 500, 800, and 1,200 mw.

4. For 250-mw expansion, the unit sizes were 150 and 250 mw.

Assumptions

1. The standard of reliability of the power system was such that sufficient generating capacity must be available so that the probability of loss of load would be 1 day in 11 years.

2. The combined forced outage rate was 2% for the generating unit (combined boiler and turbine-generator set). This is in line with recent experience on generating units. To determine the effect of possible lower reliability of very large units, a forced outage rate of 3% was assumed in some cases.

3. Each boiler-turbine-generator unit on the system would be out of service for 20 weekdays a year for planned maintenance.

4. The variation in system weekday peak load throughout the year was a straight line from 100% to 80% as shown in Fig. 5. This is reasonably typical for most power systems except for some systems in the south where the summer and winter peaks are approximately equal.

5. The installed cost of new generation varied with unit size as shown in Fig. 6. Above a size of 200 mw two cost curves were used, one with constant cost per kw from 200 mw up to the largest size considered, and the other showing a continuing decrease in cost per kw above 200 mw.

6. Fixed charges on the investment were 12% per year.

7. Operating labor cost in mills per kw-hour varied with size as shown in Fig. 7. Maintenance cost in mills per kw-hour varied with size as shown in Fig. 8.

8. The heat rates of the various sizes of units were as shown in Fig. 9. Above 200 mw, the heat rate was assumed to be constant as it was thought that these larger units would all use the maximum practical steam conditions and that no improvement in heat rate would be realized only from increased size. It is realized that unit heat rates, particularly in the larger size units, will almost certainly continue to improve in the future and this improvement will make the use of larger generating units more attractive.

9. The fuel cost 25 cents per million Btu.

10. The load duration curve of the system was as shown in Fig. 10. This curve is based on a system load factor of 60% which is typical of many large power systems.

11. The fuel and operating costs of units kept on spinning reserve with negligible load factors were neglected.

Method of Analysis

The method used to determine the most economical pattern of system expansion consists essentially of two parts:

1. The determination of the reserve capacity required on the system to maintain the assumed standard of reliability for each pattern of system expansion, taking into account the following factors:
   a. Size of generating units.
   b. Forced outage rate of generating units.
   c. Weekday peak load duration curve.
   d. A planned maintenance program.

2. The application of the assumed cost factors to each pattern of expansion (taking into account the reserve capacity required) to determine the most economical pattern of expansion.

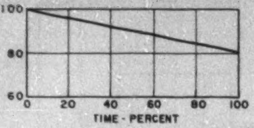

Fig. 5. Variation in system weekday peak load

The following is a brief outline of the procedure followed in carrying out the two steps. A more detailed procedure is given in Appendix I.

For each combination of generators, consisting of the old existing generators (amounting to 2,000 mw) and all new generators added to the system in accordance with the foregoing patterns of expansion, the probability of availability of particular amounts of generation was determined. This was done for each pattern of expansion using a 2% forced outage rate and also for the 8% to 5% and 10% to 7% patterns of expansion using a forced outage rate of 3% for all units over 250 mw. Since the smallest unit on the system was 25 mw, the probability of availability was determined in 25-mw steps to the point at which the probability of availability was practically zero (actually 0.00000001).

It was necessary to take into account a program of planned maintenance which would require each generating unit to be out of service for 20 weekdays per year. In planning this maintenance program, the weekday peak load throughout the year was assumed to vary as a straight line from 100% to 80% as shown in Fig. 5.

As far as system reliability is concerned, it was assumed that the total load can be considered as the actual system load plus the capability of generation out of service for maintenance. Therefore, using the peak load variation curve already referred to, the maintenance period of each machine on the system was scheduled in such a manner that the sum of the actual load and the capability of units out for maintenance at any time was kept as uniform as possible.

When this maintenance program had been established, three different loads were assumed for each amount of total installed generating capacity. Using the probability of availability factors previously determined for each combination of generating units, it was then possible to determine, for each of the assumed loads, how many days per year there would be insufficient generating capacity available to meet the load. From these data curves could be drawn, similar to Fig. 11, indicating the probability of loss of load as a function of load for each value of installed generating capacity.

First, it was assumed that whenever a new generator was added to the system the system load was immediately increased (either within the system or by sale to outside utilities) to the point where the probability of loss of load again was 1 day in 11 years. This method essentially eliminates the factor of rate of load growth. The next step was to associate the load carrying capabilities of the various generator combinations with the rates of load growth normally encountered. In order to bracket the various rates of load growth for the country, three rates were chosen: load doubling

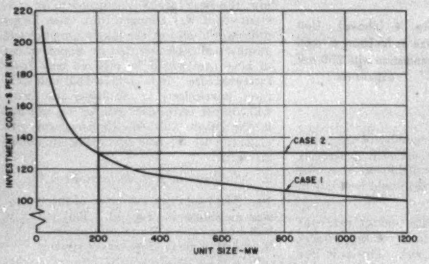

Fig. 6. Investment cost as function of unit size

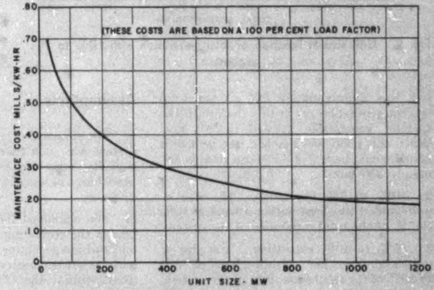

Fig. 8. Maintenance cost as function of unit size

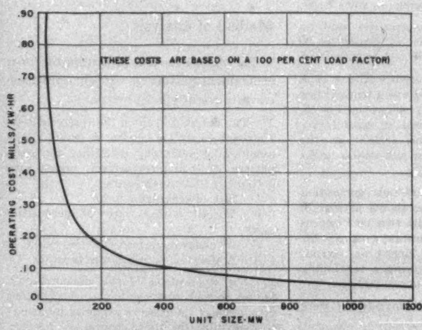

Fig. 7. Operating cost as function of unit size

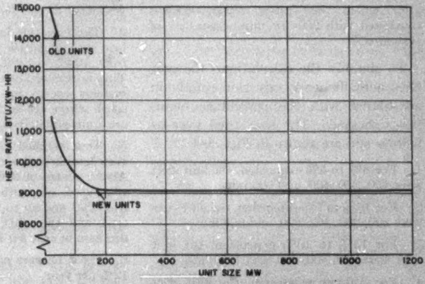

Fig. 9. Heat rate as function of unit size

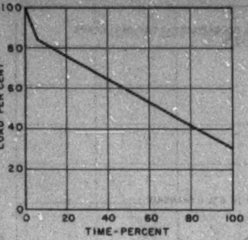

Fig. 10 (left). Load duration curve

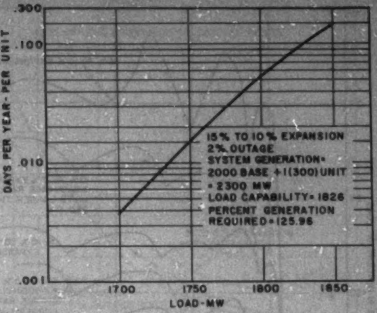

Fig. 11 (right). Probability of loss of load as function of load

in 5, 10, and 15 years. Starting with a basic system of 2,000-mw capability of generation, the load for each year was calculated for each rate of load growth until the system load was approximately 10,000 mw. In order to adhere strictly to a 1 day in 11 years loss of load probability, it was necessary in some cases to add a large block of generation when only a few additional mw of reserve were required. To be practical, in these cases, the standard of reliability was reduced to a minimum of 1 day in 7 years. No maximum standard of reliability was specified.

Table I shows the costs and the method of calculating the total annual cost of generating power in mills per kw-hour. These costs are based on the assumed curves of Figs. 6, 7, and 8 for investment, operating, and maintenance costs. Some of the units of the basic system were figured at a different investment rate than that shown in Fig. 6 as it was assumed that most of the basic system was installed at a time when investment cost was lower.

The operating costs as determined from Table I are dependent upon the utilization factor for the various machines. Utilization factor can be defined as the ratio of the kw-hours actually generated in a year by a particular machine to the maximum kw-hour capability of the machine. To calculate the utilization factor of each machine, a system load duration curve was assumed as shown in Fig. 10. This curve is based on a system load factor of 60%. It was assumed that each new unit added to the system would be base loaded. With a maintenance period of 20 weekdays per year and a forced outage rate of 2%, each new unit could supply about 90% of its total kw-hour capability. By filling in the area under the load duration curve with the generators associated with a particular load, the utilization factor for each size machine on the system was determined.

Discussion of Results

Figs. 12 and 13 are plots of the installed generation required to meet various loads with a probability of loss of load of 1 day in 11 years and 1 day in 7 years respectively. These curves are for each of the various patterns of expansion studied and take into account a program of planned maintenance. These curves do not consider the effect on the capacity requirements of the load variations that result from changing business and weather conditions. It was found that, when the effect of these load variations is included in the calculations, the reserve requirements are increased to a larger extent with smaller % expansions than for larger % expansions.

It is apparent that there is a large difference in the reserve capacity required, depending on the size of generating units added to the system. To justify economically the use of the larger units, the extra costs associated with the increased reserve must be overcome by lower invest-

ment, operating, and maintenance costs for the larger units.

Fig. 14 compares the cost of supplying the load for the four different patterns of system expansion assuming a probability of loss of load of exactly 1 day in 11 years. These curves are based on the assumption that the forced outage rate is 2% regardless of size and that the installed cost of new units continues to decrease as the size increases. For the assumed conditions the cost curve using units of 15% to 10% of system size falls below the cost curve using units of 10% to 7% of system size for system loads above 5,500 mw.

The effect of assuming that the installed cost per kw of units above 200 mw remains constant regardless of size is shown in Fig. 15. These curves indicate that for this condition expansion with 250-mw units is generally most economical.

The results shown in Figs. 14 and 15 indicate that the most economical pattern of system expansion is very dependent on the investment cost of larger generating units. It is apparent that the future slope of the cost per kw versus size curve will be a major factor in determining the economic feasibility of larger generating units.

The effect of an increase in the forced

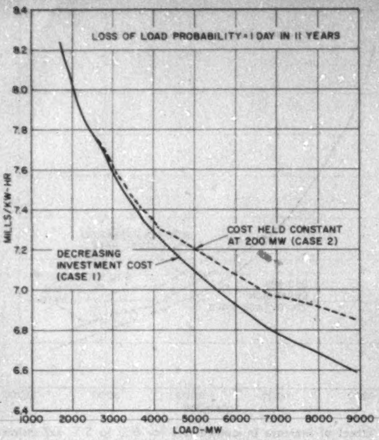

Fig. 20 (left). Effect of change in investment costs on 8% to 5% expansion

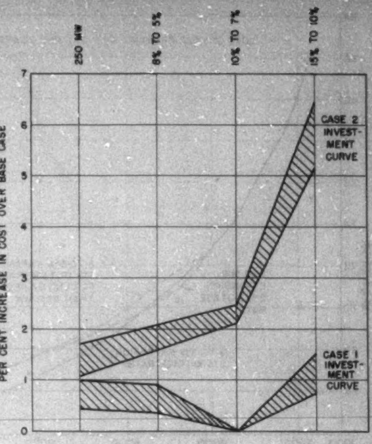
Fig. 21 (right). Comparison of present worth cost of various expansion patterns with 2% forced outage rate



outage rate of generating units larger than 250 mw from 2% to 3% is shown in Figs. 16 and 17 for the case where the investment cost per kw continues to decrease as size increases. Figs. 18 and 19 show a similar comparison for the case 2 investment cost curve of Fig. 9. It is more economical to expand the system with 250-mw units than with units of either 8% to 5% or of 10% to 7% of the system size, if the forced outage rate for units greater than 250 mw increases to 3%. If machines much larger than those produced today are to be economically justified their forced outage rates must be approximately the same as those of present machines.

Fig. 20 shows a comparison of the cost of power in mills per kw-hour using the two different assumptions for installed cost of generation as shown in Fig. 9. This comparison is for the 8% to 5% pattern of expansion using a forced outage rate of 2%.

When the rate of system load growth is taken into account, the results are not so clearly defined as were the results obtained by assuming that whenever a new generator was added to the system the system load was immediately increased (either within the system or by sale to outside utilities) to the point where the probability of loss of load was 1 day in 11 years. When the load follows a particular pattern of increase, each generator added causes a peak in the cost curve, the magnitude of which is dependent upon the percentage of the generator output that is actually required by the load.

To effect the comparisons between the various patterns of expansion when considering different rates of load growth, present worth evaluations were utilized. In brief, the present worth figure for a given expansion indicates the total amount of money that would have to be available at the present time in order to finance completely the investment and operating costs of the generation under consideration for a given period of time.

A summary of the relative costs of the different patterns of system expansion on a present worth basis using an interest rate of 4% is shown in Table II. The figures in the table indicate the percentage increase in cost over the indicated base case. Table III is a similar comparison using an interest rate of 0%.

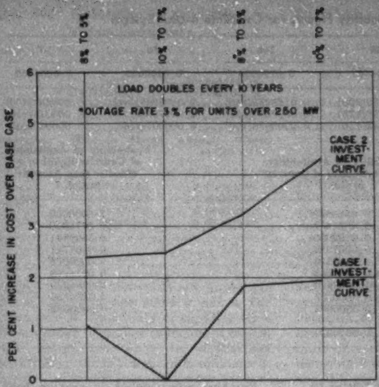

Fig. 22 (left). Effect of increase in outage rate on present worth of cost of various expansion patterns (load doubles every 10 years)

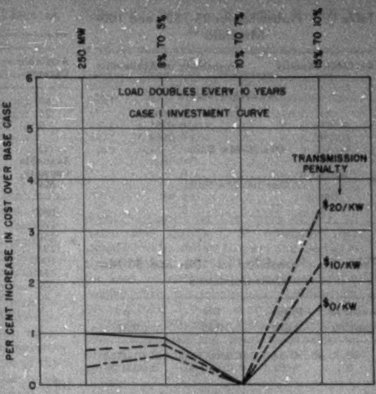
Fig. 24 (right). Relative effect of penalty in transmission system cost to provide additional transmission facilities for larger units



II are also shown graphically in Fig. 21 for a forced outage rate of 2%. The results for the three different rates of load growth all lie within the indicated band of results.

Fig. 22 shows the effect of an increase from 2% to 3% in the forced outage rate of generating units larger than 250 mw. These comparisons are for the case in which the load doubles every 10 years.

Effect of Improvement in Generating Station Heat Rate Resulting from Future Technological Advances

In all the comparisons made so far, the heat rates of all new generator units added to the system were assumed to be as given in Fig. 9, and no heat rate improvements in this curve resulting from future technological advances were considered in the calculations. However, it can reasonably be expected that there will be a continued improvement in station heat rates in the future as there has been in the past. This improvement in station heat rate will make larger units more attractive economically. The reason for this is that each new unit added to the system will be base loaded during the early years of operation and so the load on the older, less efficient units can be reduced. The larger the new unit that is added, the greater the fuel saving realized on the older units and this fuel saving can be used to more than offset the extra costs incurred due to the extra reserve required for the larger units.

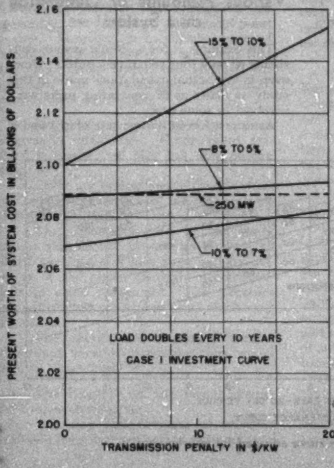


Fig. 23 (left). Effect of penalty in transmission system cost upon present worth of system cost

Effect of Larger Units on Transmission System Costs

In the results presented so far only the total costs of generating power have been considered. However, the use of very large generating units will require additional transmission facilities to provide support in case of planned or forced outages of a generating unit. It is estimated that for a widespread, well-designed system the incremental cost of providing such additional transmission facilities will be between $10 and $20 per kw of installed capacity for 1,000-mw generating units as compared to 250-mw generating units.

To explore the effect of the cost of providing additional transmission facilities for the larger units, two cases were considered by modifying the investment costs of units as a function of unit size as follows:

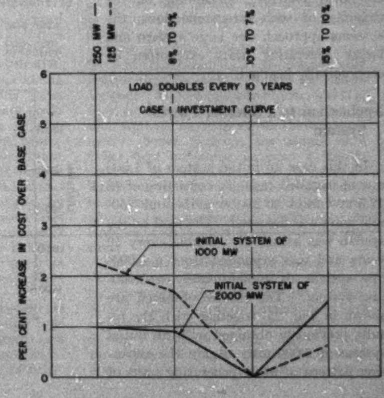

Fig. 25 (right). Effect of using initial system of 1,000 mw instead of 2,000 mw

	1.0000000	

1. The penalty in cost for supplying additional transmission facilities was assumed to vary linearly from $0 per kw for 250-mw units to $10 per kw for 1,000-mw units.

2. The penalty in cost for supplying additional transmission facilities was assumed to vary linearly from $0 per kw for 250-mw units to $20 per kw for 1,000-mw units.

The effect of the penalty in transmission costs on the present worth of system costs is shown in Fig. 23. In this case it was assumed that the system load doubled every 10 years. It can be seen that any appreciable extra cost in the transmission system considerably reduces the attractiveness of larger generating units. The same results are shown in different form in Fig. 24.

Interconnecting transmission facilities between systems can often be economically justified on the basis of economical power interchange and of the reduction in total reserve capacity required on the combined systems. Depending on the capacity of such interconnections, the systems approach one large system and larger generating units can often be economically justified.

Application to a Smaller Power System

In this case an initial system of 1,000 mw of installed capacity consisting of 12 12.5-mw units, 20 25-mw units, and 7 50-mw units was assumed. The load on the system was assumed to double every 10 years and was expanded from a 1,000-mw system to approximately a 5,000-mw system. The results obtained are shown in Fig. 25, together with the results previously obtained with an initial system of 2,000 mw. Again the expansion pattern of using generating units of 10% to 7% of system size was found to be the most economical but the reduction in cost by using this pattern rather than smaller units is greater for the smaller system. This result was obtained because the slope of the cost per kw versus size curve is steeper in the lower size range. There is therefore a greater gain in using units that are a higher percentage of system size on a small system than on a large one.

Summary of Factors for and Against Large Generating Units

The factors in favor of and against the use of large generating units may be summarized as follows:

Factors Favoring Large Units

1. A steep slope of the curve of cost per kw versus size.
2. Lower operating and maintenance costs per kw-hour for larger units.
3. Further improvement in station heat rate resulting from technological advances.
4. Reduction in the number of construction and maintenance crews required with larger units.
5. Interconnections with adjoining systems.

Factors Against Large Units

1. Flat slope of the curve of cost per kw versus size.
2. Increased reserve capacity required with larger units.
3. Any increase in forced outage rate.
4. Increase in capacity required in the transmission system.
5. Site limitations.

Appendix I. Example of Method Used in Determining the Probability of Availability of Various Amounts of Generation on a System[1]

This example is for a simple system consisting of only four generating units. However, in the actual calculations made in this study as many as 67 generating units were involved in some cases.

Assume a forced outage rate of 2% and a

system composed of two 25-mw units, one 50-mw unit, and one 100-mw unit. The probability of availability of capacity for a given number of similar units and a chosen fixed outage rate may be determined directly from the tables given in reference 2. Table IV gives the information for the system chosen. The probability of availability of the combination of the 100-mw units and the 50-mw units may be determined as given in Table V. Similarly the probability figures for the complete 4-unit system are obtained as shown in Table VI.

The following is an example of how the planned maintenance program was taken into account in determining the reserve capacity required. In this case the installed capacity on the system consisted of 12 25-mw units, 20 50-mw units, 7 100-mw units, and 1 300-mw unit for a total of 2,300 mw. A selected portion of the probability of availability figures for this system of generation is given in Table VII. A system weekday peak load of1,800 mw was assumed and it was also assumed that the weekday peak load varied linearly with time to a minimum weekday peak of 80% of the maximum peak or 1,440 mw.

Fig. 26 shows this peak load variation and also shows how each machine on the system was scheduled for planned maintenance for 20 weekdays per year. The number on each block indicates the mw capability of a machine and outages for maintenance were scheduled so that the sum of the actual load and the capability of the units out for maintenance was as uniform as possible. With this maintenance schedule established, the number of weekdays during the year that the load plus the generation out for maintenance fell within each 25-mw load band was determined.

From Fig. 26 the information given in Table VIII was obtained. The number of days per year that it would not be possible to meet the load was then determined as shown in Table IX. This gives one point on the curve shown in Fig. 11.

The foregoing procedure was repeated for two other values of peak load; in this case 1,750 mw and 1,700 mw are two other points obtained for the curve of Fig. 11. Since the standard of reliability was assumed to be ability to carry the load at all times except 1 day in 11 years, Fig. 11 can be used to determine what load can be carried with this reliability. Reading Fig. 11 at 0.0909 day per year gives a load of 1,826 mw. Since the installed generation was 2,300 mw, the total generation expressed in terms of the load was 126% of the load.

Discussion

O. R. Bulkley (Southern California Edison Company, Los Angeles, Calif.): The authors are to be commended for a very thoughtful and painstaking analysis of this timely subject. Based on the assumptions given, it would appear that the conclusions are reasonable, from a strictly theoretical point of view. However, in considering units of the large sizes mentioned, it is evident that other controlling factors would limit the sizes that can economically be justified. Some of these factors are:

1. Size must not run ahead of our proved progress in metallurgy. From recent evidence it seems that size has now outrun progress.
2. There are limitations to the practical and economic capacity of interconnections with other utilities.
3. The economics used in the study assume that it will always be possible to absorb the load of a new large unit by disposing of the power through interconnections to other companies. This becomes more difficult in practice as units reach very large sizes.
4. The practicability of using the largest of perhaps several alternative sizes would seem to depend on:

   a. The reserves on the prime system itself to cover outages.

   b. The size and firmness of reserves available from interconnected systems.

If the prime system has such reserves that it can cover an outage of the largest unit without shock then there is no operating problem but there may be an economic one. If the prime system has large enough ties with other systems so that it could lose the use of its largest machine without shock, there may be no problem at all. If, however, neither of these provisions is available, very large generators could be a serious handicap during forced outages.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): This study brings out a number of interesting points, including a demonstration that probability calculations play an important part in determining the economic size of generating units. The comparisons of the various schemes could not be achieved without the use of such calculations. We have been using probability calculations as one of the important factors in determining the required reserve generating capacity, and these calculations are based on the methods developed by Adler and Miller.[1] This approach not only gives us an idea of the magnitude of outages for various time intervals but also gives information on the probable duration of outages, particularly the larger coincident forced outages.

The authors assume for the general case that the forced outage rates for unit-type installations of turbine generators and boilers would be 2%, although some calculations are based on 3%. A study of reference 3 of the paper for operating experience for turbines and boilers operating at over 1,000 pounds per square inch gauge indicates that the average combined rate of outages for the years 1950–1952, in percentage of the time that the units could be operating on weekdays, is more of the order of 3% than 2%. I hope it does definitely get down to the level of 2% or lower that the authors mention. There were lower rates of outages in 1951 and 1952 than in 1950, but other operating experiences before and after that period make it seem imprudent to use the relatively low rates of one or two years.

As is generally known, the outage rates for unit-type installations are considerably greater than for systems where the boilers are connected to a common header, which in turn supplies two or more generators. In such stations, especially when there is some reserve boiler capacity, the outage of a boiler does not cause as great a loss in capacity as with the unit-type system. Furthermore, the older and smaller units have been having lower rates of forced outages than apparently applies for the large units and boilers in unit-type installations.

For several years it has appeared to me that the sum of the load plus the allowance for overhauling plus the allowance for limitations (due to decreased summer-time load capabilities) should be a constant figure during a 12-month period. Apparently in the authors' study the effect of limitations is not considered, but they may amount to a loss of 2 to 5% in capability, or even more, in the summer as compared to the midwinter capability.

In connection with Fig. 26, where the authors show provision for overhauling on top of the range of daily load peaks during the year, it does not seem practically feasible to do what they have done. For example, in any given month of the year there may be a range in the magnitude of weekday peak loads of 10 to 15%, depending on the influence of relative darkness, temperature, and other factors on the load demands. Our studies do show that there is at present an appreciable range through the year in the monthly peak loads. In handling the allowances for overhauling and limitations, we build these allowances on top of the monthly peak demands.

In connection with the previous point, we do take a small advantage of the fact that the larger totals of forced outages are likely to persist just a day or two. This is done first by taking into account our results of studies of past loads, which show that for about 90% of the weekdays of a given month the daily peak loads have been about $1^{1}/_{4}\%$ or more below the monthly peak loads. This value, in mw, is then deducted from the indicated owned reserve that is needed according to probability calculations and other factors. The value of $1^{1}/_{4}\%$ just given applies for the winter months and the corresponding value for summer is larger.

A practical view from the standpoint of operation is to consider the possibility of relieving tight situations created by large simultaneous outages. With relatively smaller units, large simultaneous forced outages generally will not occur suddenly but will be built up to their full magnitude in successive steps in time. This makes it possible to make arrangements to return equipment to service more quickly than originally planned, in case the total of the forced outages is building up to a disturbing amount. This ameliorative measure cannot be used so effectively when the system consists of very large units where each corresponds, say, to 10% of the total system capacity.

It does not seem appropriate to comment on all the assumptions and points in this article, but a majority of them appear to be fairly reasonable. For large turbine generators, however, it seems probable that there should be an allowance for overhauling of more than the 20 weekdays mentioned. In connection with the discussion on the benefit of interconnections in reducing the reserve capacity, probability calculations, or at least some judgment, should be applied as to how much the firm power will be in case of a large outage of generating capacity. It is of interest to note that the authors use an increased rate of forced outages in one set of their calculations where the size of units goes over 250 mw.

Another point to be considered in connection with the installation of larger and larger units over a period of time is that some probability calculations need to be made to determine the possible effects of having larger than the average sized unit on the system out of service during forced outages. Two calculations on the probabilities of forced outages of a given number of units showed that, where the failed units were relatively large in size, the magnitude of the coincident forced outage was one-third bigger than for the case involving outages of just average sized units. The authors' paper demonstrates the value of using a digital computer for such studies where there are a large number of repetitive probability calculations.

1. A New Approach to Probability Problems in Electrical Engineering, H. A. Adler, K. W. Miller. *AIEE Transactions (Electrical Engineering)*, vol. 65, Oct. 1946, pp. 630–32.

C. F. Paulus (The Cleveland Electric Illuminating Company, Cleveland, Ohio): I very much enjoyed this paper, which was incisive and specific. There are several points I would like to mention.

What is included in the investment base and what rating is used in calculating the costs per kw? Possibly the equipment included should be enumerated and the rating, net or gross name plate, or capability.

The heat rate curve shown in Fig. 9 seems unduly pessimistic. This kind of curve has been shown for the last 25 years always flattening out at the size corresponding to the largest unit installed at that date. Certainly heat rates appreciably below that shown are possible. The added complications they introduce may well be justified with the larger units.

Throughout this paper there is the implication that the larger spinning reserve required with the larger units has no value; that it is an unwanted accompaniment. This extra capacity is of the highest efficiency and does have real value. The spinning reserve consists of the older units while the newest unit is fully loaded. The larger unit should be credited for the improvement in system efficiency. The larger spinning capacity on a system with larger units is useful in case of a plant shutdown. The magnitude of the net deficiency is reduced. I believe that the record of the last few years indicates that plant shutdowns are still with us.

Complete unitization of turbogenerators is still too costly. This is especially true when applied to small units. I am thinking of a system of a size where the application of the authors' formula would indicate about 100-mw units whereas units of about 300 mw appear more economical. In a plant of 600 mw, complete unitization for two 300-mw units may be justified. This would be difficult to do for six 100-mw units. The completely unitized 2-unit plant is more likely to keep some capacity on the line than is the nonunitized 6-unit plant.

The time required for an overhaul or inspection of a large unit is but little more than for a small unit. If the time required for scheduled maintenance is integrated into the reserve requirement calculations, the larger additional capacity required by larger units compared to smaller units is reduced.

A tabulation of the ratios of unit sizes to installed capacities shows that at the time the horizontal turbogenerator was introduced new units were as large as 50% of the installed capacity. The presently foreseeable growth of the electric power industry should give us confidence that additions of 20% or so are not excessive.

H. W. Phillips (Philadelphia Electric Company, Philadelphia, Pa.): This paper investigates the most economical machine sizes for future installation on an isolated system. The conclusions are reached by comparing the gain in operating economy and reduction in investment cost through the utilization of large units. The analysis fails to take into consideration the fact that the installation of a larger unit on an isolated system will, in most cases, require an increase in the spinning reserve capacity.

Experience on the Pennsylvania-New Jersey Interconnection during the last 25 years has indicated that the companies doing the best daily load forecasting have a probability of loss of load through daily load forecasting errors amounting to about once every 8 years, if 5% spinning reserve is scheduled. This frequency of loss of load once every 8 years is in line with the two analyses included in the paper covering a frequency of once every 7 years or once every 11 years. Therefore, it seems that the standards of the Pennsylvania-New Jersey Interconnection are quite paralleled with those assumed in the paper.

The hypothetical system used in the analysis has a basic load of 2,000 mw, and 5% spinning reserve would amount to 100 mw or approximately equal to the largest unit installed initially (100 mw). Based on the experience of the Pennsylvania-New Jersey Interconnection, where 30-mw units are used to make up any deficiency in spinning reserve, the daily cost for this reserve adjusted to fuel at 25¢ per million Btu would be $9.40 per mw day. This would represent an increased daily operating cost of $940 if a 200,000-kw unit were installed. If it is assumed that no additional spinning reserve is normally required on Sundays, the incremental extra spinning reserve cost would be applicable for approximately 300 days per year, and would amount to $282,000 per year. Therefore, it seems very difficult to justify doubling the size of the largest unit on an isolated system when the largest unit presently installed is equal to the daily load forecasting error hazard.

These comments have been based purely on the application of the conclusions of the paper to an isolated system; however, few electric utility companies are isolated today, and many of them have entered into pooling agreements through which the installed reserve and spinning reserve can be greatly reduced and much larger machines justified. The Pennsylvania-New Jersey interconnected system having a load of approximately 7,000,000 kw carries spinning reserve equal to $4^{1}/_{2}\%$ of the annual peak load, or 315,000 kw. This gives a probability of loss of load due to daily load forecasting errors of once every 8 years; however, two of the companies in this group have ordered units in the 225 to 275-mw class because it is possible to operate these units without additional spinning reserve. Furthermore, at the present time a 315-mw unit would be justified since it would not exceed the spinning reserve required by the daily load forecasting hazard. The probability of losing this unit at the time that the $4^{1}/_{2}\%$ load forecasting error occurred (on a 2-hour peak) would be only once in approximately 10,000 years.

Figs. 12 and 13 indicate that installed reserve of 22 to 23% would be required if the 10% to 7% expansion rate were utilized.

However, a 315,000 unit on the Pennsylvania-New Jersey system would amount to 12½% of the load of the largest system and 30% of the load of the smallest system in the area, but could be installed without increasing the Interconnection installed reserve requirement above the present figure of 10%. This is made possible through a very complete pooling agreement whereby the various companies pay at a very reasonable rate for any deficiency in their installed reserve obligation.

It is felt that if the problem were restudied, considering the possibilities available through well-co-ordinated Interconnection, the installation of units in the 10% to 7% range would prove too small and that units of greater size could be justified.

Howard P. Seelye (The Detroit Edison Company, Detroit, Mich.): A study like this may have some value in indicating trends or areas for specific investigation. It is unlikely, however, that it could be depended upon as the basis of any choice of generator size. Conditions are so different on different systems, both as to loads, transmission, interconnections, and construction costs, that a specific determination for any proposed installation is believed to be necessary.

In general, the conclusion that generators of 10% to 7% of the size of the system will be found economical is fairly well in agreement with the results of specific studies on the Detroit Edison System whereby a 260-mw unit was chosen for a system load of 2,500 mw, and a 300-mw unit as the next step a couple of years later.

Figs. 12 and 13 seem to indicate rather higher amounts of reserve generation than is believed to be necessary in practice, running from about 18% to as much as 30%. This is probably a result of the method of calculation used. Studies made for our system several years ago, using probability methods, but based on the frequency of expectation of a combination outage exceeding the load, indicated that within certain limits of practicability, the reserve required is a percentage of the load, which percentage decreases in an increasing number of units, but has little relation to the size of unit, provided that latter is not excessive compared with the size of the system. This would indicate less reserve necessary and less effect of the size of units than is indicated here. The effect of pool operation of interconnected systems has a great deal of bearing on the size of unit which may be justified. Other assumptions as to variation of cost of installation with size, variation in maintenance cost, variation in operation, variation in heat rate, etc., are all so dependent upon specific design conditions that it is hard to judge whether or not the results indicated are truly representative. As a general indication, however, of the value of reasonably large units on a system, this study is in the right direction.

M. J. Steinberg (Consolidated Edison Company of New York, Inc., New York, N. Y.): This paper describes a method of analysis relating to the economic evaluation of capacity additions to an electric system. The paper is of timely interest because of the attention currently being given to the problem of unit additions with maximum capabilities in the range of 300 mw. This problem is usually resolved on the basis of an analysis which attempts to evaluate all factors, tangible and intangible, that influence the relative economics of all alternatives under consideration. In general, the comparison of alternatives will be made with reference to a base case, which will usually be the one that requires the least investment. Differentials of annual operating savings are balanced against differential investments and final results are tabulated to show either the rate of return on added investment or the added investment that can be justified by the differential operating savings in relation to the estimated actual investment.

Attention is called to a comprehensive treatment by Skrotzki[1] of the fundamentals involved. The procedure described by the authors follows, with some modifications, the procedure recommended in the Skrotzki paper which in my opinion merits careful study by those interested in this field of activity.

The effect of unit size on installed reserve capacity requirements is of special interest. Although the literature on this phase of the problem is quite meager, there is enough to indicate that there are at least two schools of thought. One point of view is that unit size does not affect reserve capacity requirement. This stems from the policy which plans capacity additions to provide installed system reserve capacity equal to a fixed percentage of the peak load demand. The position taken is that no penalty attaches to a unit because of size, unless the size of the unit exceeds the total installed reserve capacity. This view has been upheld in a recently published article[2] which states: "It might be inferred that a larger unit would require somewhat more system reserve to provide against its outage than would a smaller one. Reserve is considered in terms of a percentage of system load, however, so if this indicates an amount as great as the size of the unit, no additional amount should be necessary..."

The opposite point of view is that system reserve capacity requirements increase with the addition of larger sized units, a characteristic which is generally the result when reserve requirements are determined by the application of probability mathematics. This is clearly demonstrated by the curves of Figs. 12 and 13 and confirmed by the curves of Fig. 27 which was prepared on the basis of uniform size unit additions. It will be observed from Fig. 27 that, with successive unit additions, there is an increase in the % reserve capacity requirement until a maximum value is reached, with the percentage values decreasing thereafter. It will also be noted that the rate of increase of reserve requirement to the maximum value varies with unit size. Thus, for a given peak load growth, the number of unit additions will decrease with unit size, while the required total capacity addition will increase with unit size, so that the total investment will also increase with unit size, and this increase in investment for the larger units must be justified by the annual savings which will result from the increased generation and improved thermal efficiency if the latter is obtained.

As between the two views on the method of determination of objective reserve capacity requirements, I favor the one which is based on the application of probability mathematics, first, because it is based on sound mathematical principles in use by the telephone industry for many years before adoption by several of the larger electric utilities, and second, because it introduces a discounting factor against the added investment for the larger size units to offset the imponderables which are inherent in long-range estimates into the future.

For most electric systems the annual generation of the initial unit addition will be affected by subsequent unit additions. In the early years of service it is expected that the initial unit will be base-loaded, with reduction in annual generation thereafter as

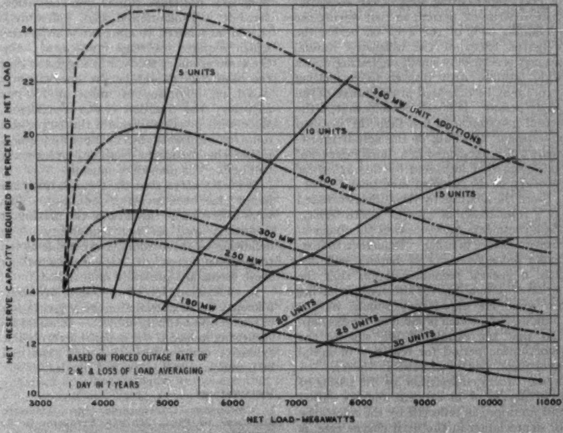

Fig. 27. Effect of unit size on installed reserve capacity requirements

Table X. Evaluation of Savings as a Function of Age

At 6% Interest

Years	Capacity Factor, %	Efficiency Factor	Relative Savings, %	Present Worth Factor	Present Worth of Annual Savings, %
1 to 5	80.00	1.00	80.00	4.2124	336.9920
6 to 10	77.23	0.99	76.46	3.1478	240.6808
11 to 15	63.19	0.98	61.93	2.3522	145.6717
16 to 20	53.49	0.97	51.89	1.7577	91.2071
21 to 25	48.20	0.96	46.27	1.3134	60.7710
26 to 30	43.39	0.95	41.22	0.9815	40.4574
31 to 35	41.08	0.94	38.62	0.7334	28.3239
36 to 40	38.17	0.92	35.12	0.5481	19.2493
41 to 45	36.13	0.90	32.52	0.4095	13.3169
45 to 50	32.91	0.90	29.62	0.3060	9.0637
Present worth of total annual savings					985.7338
Fixed charge rate					13%

Investment justified by annual savings $= \frac{985.7338}{0.13}\left[\frac{0.06(1.06)^{50}}{(1.06)50-1}\right] = 4.8028$

Ratio—justified investment to savings in first year $= \frac{4.8028}{0.80} = 6.0$

more units are added to the system. This results in non-uniform annual operating savings which decrease with service years. Conversion of the nonuniform annual savings to equivalent present worth values is a conventional procedure, which can be utilized to establish the relation between the savings in the first year of operation and the investment that can be justified for the initial unit if the simplifying assumption that annual savings will vary approximately in direct ratio to the annual generation or capacity factor is acceptable. A sample calculation along this line is given in Table X. Such a calculation is useful in evaluating differentials of operating costs of equal size units as affected by the proposals offered by manufacturers of equipment.

The rate of recovery of capital investment through operating savings is greater in the early years of the service life due to the greater utilization of the unit. Fig. 28, derived from the values of Table X, indicates the percentage recovery of the total justified investment as a function of age. It will be noted from Fig. 28 that 83% of the justified investment is recovered in a period of years representing 40% of the amortization or write-off period, so that during the remaining 60% of the write-off period the weighted effect of the estimated annual savings is relatively small, suggesting that a wide latitude with respect to estimating errors may be tolerated in this range of the study period. It is also obvious that, if the actual investment is less than the justified investment, the bulk of the actual investment will be recovered in a shorter period of time than that indicated by this figure for recovery of the justified investment.

Since the analysis by the authors is based on a comparison of present worth values, some comments on the use of this basis of comparison are in order. Reference to textbooks on engineering economics will disclose a general recommendation that the period of comparison for alternatives having the same life expectancy should be the estimated life, which is based on the assumption that the estimated life will be the amortization period for recovery of initial investment with a return thereon. A present worth comparison for the period of amortization of investment for the initial unit addition, as reflected by the allowance for depreciation in the fixed charge rate, is suggested. It is inferred that the authors have used different periods of comparison for each rate of load growth in arriving at the values shown in Tables II and III. This follows if the authors have limited their calculations to the number of years required for the system load to increase from an initial value of 2,000 mw to a final value of approximately 10,000 mw. Thus for loads doubling in 5, 10, and 15 years, the annual rates of load growth have been computed as 14.9%, 7.2%, and 4.7% respectively, requiring 12, 23, and 35 years to reach the 10,000-mw value. In view of the very small percentage differentials shown in these tables, the use of a relatively short period of comparison casts some doubt on the conclusiveness of the results. Expression of opinion on this point would be most welcome.

With reference to the same tables, it is noted that the authors have used as the base case for reference the 10% to 7% expansion, presumably because the present worth of the combined annual fixed charges and operating costs is the minimum, and this is used as the basis for the conclusion that this plan of capacity expansion is the most economical. Actually, this is not conclusive, since it is fundamental that differentials should be referred to the plan of expansion which requires the least investment. For the systems under study, it is suggested that the base case should be the one which is based on additions of units of 150-mw capacity, the smallest units considered, since with penalties against the larger size units for additional reserve capacity requirements the minimum practical investment will be for this plan of expansion.

It is also noted that the term "utilization factor" has been incorrectly defined. This term is defined as the ratio of the maximum generated load to unit capability. The definition by the authors is applicable to the terms "use factor" or "capacity factor" as these terms are generally understood.

In conclusion, I wish to extend my compliments to the authors for the presentation of a paper on a timely subject. It would be surprising indeed if the paper does not elicit extensive constructive discussion that will be beneficial to all interested parties.

2. ECONOMY OF LARGE GENERATING UNITS, **H. P. Seelye, W. W. Brown.** *Combustion*, New York, N. Y., vol. 25, 1954.

C. W. Watchorn (Pennsylvania Water and Power Company, Baltimore, Md.): The paper is another valuable contribution to the growing list of examples or illustrations of the application of probability methods to power-system problems. The authors are to be most highly commended both on undertaking a very ambitious project and in making the results available to the industry. The real value or significance of the paper is in its illustration of the applicability of probability methods as a tool in the solution of economic problems of power-system design rather than with respect to the specific results reported. The material is long overdue both as such an illustration and as a demonstration of the applicability of digital computers to the handling of the vast amount of arithmetic that is inherent in such problems. This latter fact should remove much of the past reluctance as to the use of probability methods in the solution of power-system problems to which such methods are applicable.

I wish to make a few specific comments relative to various aspects of the details of such evaluations, the first regarding the determination of the timing of the installation of additional capacity. Several years ago I wrote that an acceptable and satisfactory objective level or degree of system reliability should be in the order of an average rate of failure to carry the load of 1 day in about 30 years if the effect of load variations or so-called load forecasting or estimating errors is disregarded,[1] and somewhat smaller,[2] in the order of an average rate of 1 day in about 8 to 10 years, when the effect of load variations is taken into account.[2,3] Such a basis, although possibly reasonable, is nonetheless only a matter of judgment with respect to which anyone may well take exception without there being any basis for successfully controverting any other level of objective reliability that it may be desired to propose.

More recently I proposed,[4] with concurrence by others,[5,6] that the measure of the adequacy of service continuity is the cost to the general economy of providing the service. That is, facilities should be provided up to such point that the economic burden of providing additional facilities is larger than the probable average economic gain (which is intended not to mean reductions in otherwise lost revenue[6]) that would result with increased service continuity from the installation of such additional facilities. Such a basis for the timing of the installation of additional capacity substitutes a comparison of more or less definite with and without costs as the criterion for such timing in place of an opinion as to a satisfactory level of an objective service reliability.

Also, since the studies reported are based on annual carrying charges of 12%, the cost of money involved must be in the general order of 6%.[7] It then follows that the discount rate to be used in the present worth calculations should also be about 6%;[8] there is no other choice, since it is just as essential for the discount rate that is used in the present worth calculation to be equal to that used as the cost of money in determining the annual carrying charges as it is for the I's in the equations $E=IR$ and $P=EI$ to be equal for the same condition as of any given time, because the relationships, in their respective ways, are equally rigorous. The result is that the costs of the more distant future would be discounted to a greater extent on this basis than on the basis used in the paper where two discount rates, 0 and 4%, were used. This means that the tendency may be indicated for smaller size units than otherwise to be the more economical in such a study with the timing of the installation of additional capacity based on the costs to the general economy, as just suggested.

Further, although the authors recognize the effect of load variations on the timing of the installation of additional capacity, they have chosen not to incorporate such considerations in their determination. The effect of such considerations, if included in the study, would be to tend to indicate the larger size units to be the more economical.

In addition to the bases used by the authors for determining the pattern of unit sizes to be investigated, I would suggest that an investigation of the effect of increasing and decreasing percentage patterns of size of units may have significance. Lastly, although the authors found that, "for the range of rates of load growth normally encountered, the rate of load growth of a system has no appreciable effect on the size of units that can be economically justified on a system," it nevertheless is difficult to understand why the smaller size units would not be definitely indicated to be the more economical with the smaller rates of load growth.

8. PRESENT WORTH, OR THE TIME COST OF MONEY, AS A FACTOR IN THE ECONOMIC COMPARISON OF ALTERNATIVE FACILITIES, Paul H. Jeynes. *Ibid.*, pp. 1956–62.

L. K. Kirchmayer, A. G. Mellor, J. F. O'Mara, and J. R. Stevenson: All of the discussers have contributed to a better understanding of the problem of determining the economic size of steam-electric generating units.

In answer to Mr. Bulkley's question regarding the feasibility of building much larger generating units, we have every confidence that continued progress in metallurgy and design skill will make units larger than those now in operation economically feasible. Mr. Bulkley correctly points out that in several cases studied it was assumed that it would be possible to absorb the load of a new large unit by disposing of the power through interconnection to other companies. However, in Figs. 21 through 25, and in the conclusions of the paper, this assumption was not made, and the system load was assumed to double every 5, 10, or 15 years.

We are pleased that Mr. Halperin has indicated general agreement with our assumptions. Concerning his comments on the forced outage rate used, recent figures indicate that the reliability of large high-pressure units has been improving. We therefore feel that a 2% forced outage rate is fairly representative of most large units now in service. In connection with the treatment of maintenance outages, the approximations we made will provide the correct relative results. Also, we have been advised by several operating companies that 20 weekdays per year for maintenance are more than adequate.

In answer to Mr. Paulus' question, the investment costs used are the total installed cost of the generating unit up to the high-voltage side of the main step-up transformer. The rating referred to is net guaranteed capability of the unit. As stated in the paper, it is anticipated that unit heat rates, particularly in the larger size units, will certainly improve in the future. The effect of this improvement in heat rate is discussed qualitatively in the paper. Larger size units will be required to fully realize the potential gains resulting from much higher steam pressures.

We agree with Mr. Paulus that the extra reserve capacity required with the larger generating units has an economic value in displacing higher cost generation and our analysis has appropriately considered this effect. Also, we concur that the time required for an overhaul or inspection of a large unit is little or no more than for a small unit. This factor is reflected in the maintenance cost curves of Fig. 8.

It is our opinion concerning Mr. Paulus' comments on the cost of complete utilization that most new stations are economically utilizing the unit scheme for units approximately 100 mw and above. Also, with respect to plant outages, we believe that a 6-unit station should prove more reliable than a 2-unit station.

Mr. Phillips has commented on the effect of larger generating units on the required spinning reserve capacity. We wish to point out that the only cost of providing reserve capacity which has been ignored is the fuel cost. It is felt that with the negligible load factors involved this is a reasonable assumption, particularly as the fuel used by the spinning reserve is partly compensated for by the fuel saving on other units.

In considering the subject of interconnections, a group of operating companies may be considered as one system providing that adequate interconnecting transmission facilities and agreements exist. Thus, the 10% to 7% expansion pattern referred to the total integrated area would be a much larger percentage when referred to any operating component of the total.

We are pleased that Mr. Seelye has reported that the results of the studies undertaken by his company are in general agreement with the results of our paper. We believe that each company must conduct specific studies to obtain answers pertinent to their individual systems.

Application of probability methods to choose sufficient reserve capacity to maintain a fixed service reliability results in increased % reserve requirements as the unit size increases. This point is illustrated by reference to Figs. 12, 13, and 27.

Mr. Steinberg has called our attention to the interesting paper on this subject by Mr. Skrotzki. Our approach differs fundamentally in the treatment of reserve requirements. We have attempted to maintain the same standard of service reliability for all types of system expansion while Mr. Skrotzki's approach allows a variable standard of reliability as the system expands.

Mr. Steinberg's comments on the period of time to be used in the present worth evaluations are of interest. It is our opinion that the correct relative picture is obtained by using the selected periods, and this opinion is substantiated in part by Fig. 28.

We do not agree that minimum investment cost will necessarily be realized by expanding the initial system with 150-mw units, as this depends on the slope of the investment curve used. It is our opinion that the selection of the base used has no effect on the relative answers obtained.

We concur with Mr. Watchorn that the desirable degree of system reliability is largely a matter of judgment. However, our investigations indicate that the same relative answers will be obtained over a wide range of standards of system reliability. The measure of adequacy of service continuity as a cost to the general economy involves numerous intangible factors which are impossible to include in a study similar to ours. It is necessary that each company study their own problems and find an evaluation appropriate to their system.

Mr. Watchorn has discussed the interest rate applicable for present worth calculations. We agree that the same interest rate should be used for the present worth calculations as that used in determining the rate of fixed charges. We have explored the effect of changes in this interest rate on the present worth evaluation and found that such changes had no significant effect on the relative answers obtained in this study.

Our calculations on the effect of load variations resulting from unpredictable business and weather conditions, although not included in the paper, are in accordance with Mr. Watchorn's statement that the effect of such considerations would indicate larger size units to be more economical.

As illustrated in the paper, the economic percentage pattern of generation expansion will decrease as systems become larger and the unit costs are on the flatter portion of the investment cost curve.

In our study, the effect of the assumed variation in rates of load growth were of secondary importance. It is realized that with very slow rates of load growth smaller size units would be indicated.

The discussions have indicated that there is general agreement that probability methods are a useful tool in solution of problems of this type. The more widespread availability of digital computers will make probability and general studies of this nature more feasible by reducing the time required for calculations.

The effects of interconnections on this problem have been mentioned by several of the discussers. We agree that interconnections are important considerations. Further analytical and economic investigations of interconnection benefits are now in progress.

Pumped Storage and Hydro Generation at Flatiron Power Plant

S. M. DENTON
MEMBER AIEE

H. O. BRITT
ASSOCIATE MEMBER AIEE

THE FLATIRON Power and Pumping Plant is one of a series of plants utilizing the power drop in the transmountain water diversion of the Colorado-Big Thompson Project. The Project is a Bureau of Reclamation development which diverts water from the Colorado River on the western slope of the Continental Divide to the eastern slope to provide irrigation, hydroelectric power, and other multiple-purpose benefits. The power drop of the diverted water on the eastern slope is shown in Fig. 1.

The power installation at Flatiron consists of two 35,000-kva, 514-rpm generators driven by Francis turbines, and a 2-speed combination motor-generator and pump-turbine unit. Water is delivered to the turbines of the 35,000-kva units under a net head of approximately 1,050 feet and is discharged into the Flatiron tailrace. The water used for generation must also be used subsequently for irrigation. To release water for generation throughout the year independent of the seasonal irrigation requirements, two storage reservoirs have been provided to receive the water discharged at Flatiron. One of these is Horsetooth Reservoir downstream from the Flatiron Plant. Water from Flatiron flows to Horsetooth through a feeder canal. The remaining storage is in Carter Lake Reservoir into which water from the Flatiron tailrace is pumped by the pump-turbine unit.

It was originally contemplated that the unit would operate at the same speed in both directions of rotation and that operation would change on a seasonal basis with pumping during the winter months and generation, as a feature incidental to water releases from Carter Lake, during the irrigation season. However, the 2-speed design was adopted when it became apparent that the turbine efficiency at the expected operating heads could be increased materially by changing to 257-rpm operation when generating. The value of the additional peaking kilowatts made available by the higher turbine efficiency was sufficient to make off-peak overpumping and peak load generation a profitable type of daily operation.

Description of Unit

The motor generator and pump turbine are combined in a single unit which operates at 300 rpm when pumping and at 257 rpm in the reverse direction when generating. The motor name plate rating when operating at 300 rpm is 13,000 horsepower, 13,800 volts, and unity power factor. When operating in the reverse direction and generating, the unit is rated at 8,500-kva output, 13,800 volts and unity power factor. The unit is also capable of operating as a 10,700 horsepower motor at a speed of 257 rpm and as a 10,000-kva generator at a speed of 300 rpm; however, operation at these speeds is advantageous only under abnormal head conditions and switching for this type of operation has not been provided. Should it become necessary to operate at extreme heads for extended periods, connections may readily be changed to operate as a motor at 257 rpm and as a generator at 300 rpm.

The motor-generator is conventional in that the shaft is vertical with a thrust and upper guide bearing located above the rotor and a guide bearing below the rotor. The thrust bearing is equipped with a high-pressure oil system to provide an oil film between bearing surfaces before starting to reduce the system disturbance caused by starting. A closed cooling system has been provided which consists of two water-cooled surface air coolers inside a metal air housing. Automatic carbon dioxide fire-extinguishing equipment is included.

The unusual feature of the motor-generator is in the method of obtaining 2-speed operation. There are two electrically independent and complete stator windings, one of which is used for 300-rpm and one for 257-rpm operation. Each stator winding has three main and three neutral leads brought out of the stator frame. The six neutral leads are connected to a common bus and are grounded through a distribution transformer. The main leads are arranged so that either winding may be connected to the 13.8-kv power plant bus. Physically the rotor winding consists of 24 poles. The windings on these poles are all connected in series for 300-rpm operation. For 257-rpm operation the poles are switched so that through the creation of phantom poles the effect of a 28-pole rotor is produced. Five collector rings are used to connect the field windings to external circuits for switching, and thence to the output of a direct-connected exciter through a main field circuit breaker. In addition to changing main field connections and stator windings, the switching scheme for changing from motor to generator operation also reverses the exciter field connections to permit the exciter to build up when reversing the direction of rotation.

The pump turbine operates as a centrifugal pump in one direction and as a Francis turbine in the reverse direction. There are no wicket gates and no gov-

ernor for turbine operation. The use of wicket gates was considered detrimental to pump operation and not essential for turbine operation. Water flow through the unit is controlled by a butterfly valve in the penstock. The pump is rated at 370 cubic feet per second and 240 feet head at 300 rpm and is designed for a total pumping head varying from 170 to 300 feet. As a turbine the unit is designed to operate at net heads ranging from 140 to 290 feet. The pumping head will normally exceed 200 feet and the pump is designed to obtain the best operating characteristics for heads over this value. When the pumping head is less than 200 feet the pump is operated with the butterfly valve in the discharge line partially closed, in order to improve pump operation and prevent possible overloading of the motor. Otherwise the butterfly valve is operated full open for both pump and turbine operation.

Starting, Control, and Protection

Each stator winding has its main leads connected to a 3-pole gang-operated switch mounted in a metal enclosure adjacent to the unit air housing. These switches connect to the power plant bus and are used as lead selectors for changing from motor to generator operation. They may be operated by local manual control or by remote electrical control from the main control board. The switches are interlocked to prevent both being closed at the same time. They are also interlocked so that a switch cannot be operated unless the field circuit breaker is open and both circuit breakers connecting the unit to the 13.8-kv busses are open. To change speed the main field windings and the exciter shunt field connections are switched automatically along with the switching of armature windings.

The unit is designed for full-voltage starting as an induction motor in either direction of rotation with automatic field application equipment. In the pumping direction the unit is started with the butterfly valve closed. A water-depressing system has been included to provide for synchronous condenser operation and unwatering for starting purposes. The system operates by admitting compressed air to the casing and depressing the water surface to a level below the bottom of the impeller. The depressed level is maintained until the unit has been started and is synchronized or while it is operating as a synchronous condenser. Normally the pump casing is unwatered before starting in order to minimize the system disturbance and to reduce the duty on the motor windings by shortening the starting time. However, the unit may be started with the pump casing watered whenever this is desirable. In the generating direction of rotation the turbine may be started by using the butterfly valve to control admission of water to the casing. This valve is controlled from the main control board. When starting as a turbine using the butterfly valve, the generator is brought to approximately 80 per cent of synchronous speed under control of the valve. Full voltage is then applied to the terminals with the field breaker open. The rotor accelerates to near synchronous speed by induction motor action and field is automatically applied. As an alternate to this the unit may be brought to synchronous speed under control of the butterfly valve and synchronized at normal voltage using the synchroscope. The speed is adjusted for synchronizing by adjusting both the position of the butterfly valve and the opening in a by-pass around the butterfly valve.

To provide adequate flexibility the bussing arrangement was designed so that the motor-generator could be connected through circuit breakers to either or both of the 35,000-kva generators or to the outside system, as shown in Fig. 2. This switching arrangement also permits using all the available generating capacity for starting and reduces system voltage dips to a minimum.

The two 35,000-kva generators at Flatiron are equipped with automatic voltage regulators. However, because of the relatively small capacity of the motor-generator, the voltage regulator was omitted from this unit. Machine voltage and reactive flow are controlled manually by a motor-operated field rheostat. Voltage relays furnish protection against overvoltages resulting from loss of load and overspeed. One overvoltage relay is connected across the exciter output and operates a field-reducing contactor which inserts resistance in the exciter field circuit in the event of exciter overvoltage. This is supplemented by a relay energized by machine terminal voltage. Operation of this relay trips the generator field circuit breaker. An overspeed switch automatically initiates closure of the butterfly valve if excessive overspeeds occur from either loss of power or loss of load. Upon loss of power while pumping, the unit will rapidly decelerate to zero speed and will reverse and run away in the opposite direction. The overspeed switch will then operate to close the butterfly valve. However under this condition no overvoltage problem exists. The voltage will decay to nearly zero with reducing speed but will not build up with speed in the reverse direction because of exciter residual. Field failure, incomplete sequence, and out-of-step relay protection are provided. Operation of any of these relays trips the 13.8-kv circuit breakers. Differential relays are connected to operate for faults within either stator winding. A sensitive overcurrent relay furnishes protection for faults between the motor and generator stator windings.

Plan of Operation

During abnormal water years the combination unit may be operated for extended periods as either a pump or a generator. When the water supply is normal and the water surface elevation of Carter Lake is within its normal operating range, the unit will be operated to suit system power requirements for obtaining maximum benefit. The operation may change once or twice daily from pumping to generation. During off-peak periods pumping into Carter Lake will be in excess of irrigation storage requirements. The excess water will then be released for generation during daily peaks. The value of peaking capacity compared to the off-peak value of power will more than offset the pumping and generating losses.

Performance Tests

A model of the pump turbine was built at the factory and was tested for efficiency, capacity, and general performance. Tests were made of turbine operation at 300 and 257 rpm and pump operation at 300 rpm. The motor generator was completely assembled and partially tested at the factory. These tests included measurements for determining the speed-torque characteristic of the motor, and the various saturation curves and efficiency both as a motor and as a generator. Heat run and overspeed tests for both motor and generator operation were performed in the field after completion of installation. Pump and turbine efficiencies were determined in the field using the salt velocity method.

On the basis of preliminary calculations of test results the unit has an over-all efficiency when delivering rated output as a pump of approximately 87 per cent compared with a warranted value of 84 per cent. As a turbine-driven generator the preliminary test results show an over-all efficiency of 85 per cent compared with a warranted value of 75 per cent at rated generator output. Results of the pump-turbine efficiency tests conducted in the field agreed quite closely with the results of the model tests. In general the test results and operational performance of the unit have been gratifying.

◆

Discussion

L. R. Sellers (Tennessee Valley Authority, Knoxville, Tenn.): In this brief outline of the unique features of the Flatiron Plant, the omission of wicket gates, governor, voltage regulator, and the selection of full-voltage induction start are important from the cost standpoint and should also simplify operation.

The use of the term "motor generator" to describe this unit is usually used to designate a generator shaft driven by a motor. We have called our Hiwassee unit a generator-motor since generation was its most important function. Perhaps the designation "motor/generator" or "generator/motor" should be used to describe a single dual-purpose machine.

Information on the following additional points would be of interest:

1. Relative cost of the 2-speed motor generator as compared to a single-speed design.
2. For remote-controlled, unattended stations, does the experience at Flatiron indicate that automatic speed-matching control of a penstock butterfly valve might have possibilities, assuming induction start could not be used?
3. What are the approximate inrush kva and voltage drop for full-voltage induction start from standstill as compared to field application near synchronous speed both for 35,000-kva units in operation, and for 35,000-kva units not in operation?

For the Tennessee Valley Authority Hiwassee No. 2 pump-turbine unit which will go into service late this year, induction start at 0.50 per unit volts was selected in order to reduce transmission line drop when starting the 102,000-horsepower motor. With this voltage applied, start kva will be less than 32,000, and the calculated accelerating time is about 1.5 minutes with the pump casing evacuated and the motor thrust-bearing pressurized. This start voltage was obtained by a midpoint tap on the main transformer delta windings. The start voltage will lead the run voltage by 60 degrees, which will facilitate the transfer from the start to the run circuit breaker.

S. M. Denton and H. O. Britt: We agree regarding the terminology used in the description of the dual-purpose electrical synchronous machine forming a part of the complete unit described. The term "generator/motor" appears to be the best description of such a unit. In reply to Mr. Seller's questions:

1. It is estimated that 2-speed operation of the unit increased its cost to 45 per cent over that of a single-speed unit.
2. Our experience indicates that of the two starting methods for generator operation described in the section on starting, the first is the most desirable in that fewer adjustments and substantially less time is required of the operator. Use of the butterfly valve and by-pass for manual speed-matching is a time-consuming operation compared to synchronizing with governor speed control. Flatiron Unit No. 3 has a 6-inch by-pass valve. The butterfly valve for this unit is 76 inches in diameter. Use of a larger by-pass would speed up this synchronizing operation. For automatic operation the size and control of the by-pass would be quite important. The variation of the head under which this unit will operate would present difficult problems in the adjustment of automatic synchronizing equipment for a unit of this kind. We would expect less difficulty with either an induction motor start from standstill with automatic field application, or a turbine start with full voltage applied at some reduced speed with automatic field application (such as at Flatiron), rather than with the use of automatic speed-matching, making use of the valves.
3. Information on inrush and voltage drop under the conditions outlined in Mr. Sellers' discussion is not available.

Maximum Short Circuit and Faulty Synchronizing Torques on Generator Foundations

VERNON W. RUSKIN
ASSOCIATE MEMBER AIEE

POWERHOUSE designers must provide generator foundations of sufficient rigidity to withstand any forces that may occur as a result of short circuits or faulty (out-of-step) synchronizing. In estimating the forces on the foundations, it is usually assumed that all the air-gap torque is transferred to the sole plates. This assumption neglects the inertia and elastic deformation of the frame, and introduces a factor of safety. The calculation of the maximum foundation reactions thus reduces to the calculation of the highest air-gap torques.

Whitney and Criner[1] have established equations for the air-gap torques under various conditions of short circuit and faulty synchronizing, which checked within 10 per cent (%) of actual torque measurements on a 12,500-kva turboalternator. Later papers by Kirschbaum[2] Batchelor, Williams, and Whitehead[3] modified the torque equations for double-line-to-ground faults, and gave equations for faulty synchronizing. Unfortunately, all these equations are very involved and require a series of elaborate calculations for each particular case. A number of simple empirical expressions for the torques are therefore used by some designers, but their accuracy is doubtful.

This paper develops a new and simple method of calculating maximum air-gap torques, which can be employed to provide a practical basis for foundation design.

Direction and Nature of the Forces

The air-gap torques due to short circuits and out-of-step synchronizing are of a damped oscillatory nature[1,2], and are transferred through the frame to the sole plates. The reactions on the sole plates therefore oscillate many times per second in the directions shown in Fig. 1, and constitute severe reversing live loads on the concrete.

Depending on the instant of application and the type of short circuit or faulty

Fig. 1. Direction of forces

Paper 55-173, recommended by the AIEE Power Generation Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1955. Manuscript submitted September 15, 1952; made available for printing December 6, 1954.

VERNON W. RUSKIN is with the British Columbia Electric Company, Vancouver, B. C., Canada.

Thanks for valuable criticism and suggestions are due to A. W. W. Cameron and K. McClymont of the Hydro-Electric Power Commission of Ontario, and to J. A. Langford, A. D. Avtzine, A. Ketvirtis, and E. C. L. Green of Canadian-Brazilian Services Ltd., Toronto, Ont., Canada.

Table I. Equations to Determine Maximum Torques

Type of Fault or Synchronizing	Simplified Equations in Per-Unit Torque
Line-to-line fault	$\frac{3\sqrt{3}}{2}\ \frac{E^2}{X_d''+X_2}$
Line-to-neutral fault	$\frac{3\sqrt{3}}{2}\ \frac{E^2}{X_d''+X_2+X_0}$
Three-phase fault	$\frac{E^2}{X_d''}$
Double line-to-neutral fault	$\frac{\sqrt{3}}{2}\ \frac{E^2}{X_d''+\frac{X_2\ X_0}{X_2+X_0}}\ \frac{X_2+3X_0}{X_2+X_0}$
Three-phase synchronizing	$\frac{3\sqrt{3}}{2}\ \frac{E^2}{X_d''+X_e}$
Single-phase synchronizing	$3\left(1+\frac{\sqrt{3}}{2}\right)\ \frac{E^2}{X_d''+X_2+2X_e}$

synchronizing, the generator armature current will contain different values of positive-, negative-, and zero-sequence components, as well as a d-c transient component decaying with the armature time constant. The consequent armature reaction is counterbalanced by an immediate rise in the rotor currents, since the flux linking the rotor cannot change instantly. The additional rotor currents will decay with the rotor short-circuit time constant. The interaction between the decaying rotor and stator magnetic fields and currents produces the damped oscillatory air-gap torque.

Simplifying Assumptions

To simplify the calculation of the air-gap torque, the following factors were neglected by previous authors[1-3] and will also be neglected in this paper:

1. Armature resistance.
2. External impedance.
3. Saturation and hysteresis.
4. Harmonics due to saliency, nondistributed windings, slots, etc.
5. Decay of internal machine voltage.
6. Exciter response.
7. Gradual reduction in angular displacement between system and machine during faulty synchronizing.

The alternating currents flowing in the machine circuits cause ohmic losses, which appear as unidirectional loss torque. This contributes about 10% to the total maximum air-gap torque. On the other hand, the decay of the armature and rotor currents, represented by decrement factors, will reduce the total maximum air-gap torque by roughly 10% over the first half-cycle after the instant of short circuit or faulty synchronizing. The author therefore made the following additional assumption:

8. Over the first half-cycle, the current decrements are counterbalanced by the effect of the unidirectional loss torque, and both these factors can thus be ignored.

It will be shown later that this additional assumption does not impair the accuracy of the results for practical engineering purposes.

Effect of Saliency

Strictly speaking, the neglect of saliency in accordance with assumption 4 is completely justified only in the case of a turboalternator. For a water-wheel generator, the theoretical effect of saliency can later be approximated as explained in Appendix I for the important case of a line to line short circuit.

Effect of Load

As a further simplification, the short circuit or faulty synchronizing will be assumed to occur under no-load conditions. The effect of a fault under load conditions can later be approximated by increasing the effective generated voltage by an amount equal to the voltage drop due to the leakage reactance. Further, the external load remaining on the generator after the fault will also produce a corresponding torque, which can be taken into account by adding it to the air-gap torque under no-load conditions.

Simplified Calculation of Maximum Air-Gap Torques

In general, maximum torque will occur if the short circuit or faulty synchronizing occurs at the instant when the effect of the various d-c transient currents produced is a maximum. The interaction between the d-c transient armature field with the rotor field then produces the highest fundamental frequency torque.

Basically, the method adopted by the author to compute the maximum air-gap torque is as follows:

1. The symmetrical components of the currents and voltages at the instant of short circuit or out-of-step synchronizing are sketched, and the value of the d-c transient armature currents are obtained by inspection.

2. The symmetrical components of the currents and voltages are also sketched for the instant when the sum of the voltage times current products in all phases is maximum. This instant corresponds to the instant of maximum instantaneous power, and therefore maximum air-gap torque. It can be found by inspection and trial.

3. From these sketches, the value of all currents and voltages at the instant of maximum air-gap torque are quickly obtained, and the value of the maximum air-gap torque can be computed easily.

The practical application of this method is illustrated in Appendixes II, III, and IV.

The author analyzed various possible short-circuit and faulty synchronizing conditions and obtained a number of simple equations for the maximum air-gap torques shown in Table I. It should be noted that the equations are given in terms of per-unit torque, which is the torque corresponding to the rated kva at unity power factor and rated voltage and speed of the generator.

Comparison with Measurements and Earlier Equations

To test the simplified equations developed in this paper, they were applied to two actual examples of turboalternators, and two water-wheel generators. Table II shows that in each case the torque calculated by the simplified equations was close to, and usually slightly less than, the value obtained from the earlier elaborate equations presented by Kirschbaum,[2] Whitney and Criner,[1] and Batchelor, Williams, and Whitehead.[3]

One typical empirical equation for the line-to-line short-circuit torque is a function of voltage squared and of the reciprocal of the subtransient direct-axis reactance. Applying this empirical equation to a generator with constants as given in Table II, section *C*, the line-to-line fault torque works out to 9.5 per unit. This is approximately 13% higher than the value given by the earlier elaborate equation, and 11% higher than that given by the new simplified equation.

Table II, section *B*, compares the results with actual torque measurements by Whitney and Criner, as read from oscillograph traces in their paper.[1] Both the earlier elaborate equation and the simplified equation show better than 10% accuracy for a line-to-line fault. In the case of a 3-phase fault, the simplified equation does not agree with the measured torque as closely as the earlier equation. On the other hand, the simplified equation appears to be more accurate for a line-to-neutral fault.

Table II, section *A*, compares the results with values computed by a transient analyzer, as obtained from a paper by McCann, Warren and Criner.[4] The simplified equations appear to be at least as accurate as the earlier elaborate equations in this case. On the basis of these comparisons it was concluded that the simplified equations are sufficiently accurate for engineering purposes.

Table II. Comparison of Simplified Equations with Other Equations and Tests

Type of Machine	Type of Fault or Synchronizing	Simplified Equations Per-Unit Torque	Earlier Equations[1-3] (6,7,12) Per-Unit Torque	Remarks

Nomenclature

X_d'' = direct-axis subtransient reactance
X_d' = direct-axis transient reactance
X_d = direct-axis synchronous reactance
X_2 = negative-sequence reactance
X_0 = zero-sequence reactance
R_1 = positive-sequence resistance
R_2 = negative-sequence resistance
R_a = d-c resistance of stator
T_{d_0}'' = subtransient open-circuit time constant in direct axis
T_{d_0}' = transient open-circuit time constant in direct axis
X_q'' = quadrature axis subtransient reactance
e, i = instantaneous voltage and current
E = effective (or rms) generated voltage
X_s = reactance of connected system
E_m, I_m = maximum values of voltage and current
I_1, I_2, I_0 = scalar magnitude of symmetrical components
$\mathbf{I}_1, \mathbf{I}_2, \mathbf{I}_0$ = symmetrical component vectors
Faulty 3-phase synchronizing = machine connected to the system out of phase through the three poles of a breaker
Faulty single-phase synchronizing = machine connected to the system out of phase, and only two poles of the 3-pole circuit breaker are closed

Relative Values of Short-Circuit Torques

Apart from providing simple expressions for the maximum torque, the simplified equations can be used to obtain useful generalizations regarding the type of fault that produces the highest torque for a given generator.

An analysis of the simplified equations in Table I, suggests the following:

1. Since $(X_d''+X_2)$ is less than $(X_d''+X_2+X_0)$, the line-to-line short-circuit torque will always exceed the line-to-neutral short-circuit torque.

2. Taking $X_2=1/2(X_d''+X_q'')$, approximately, it can be shown that the line-to-line short-circuit torque will exceed the 3-phase short-circuit torque, provided that the ratio X_q''/X_d'' is less than 2.2. The 3-phase short-circuit torque will exceed the line-to-line short-circuit torque if X_q''/X_d'' is greater than 2.2. This ratio is less than 2.2 for all turboalternators and for most water-wheel generators. The line-to-line short-circuit torque will therefore normally exceed the 3-phase short-circuit torque.

3. Similarly, it can be shown that the line-to-line short-circuit torque will exceed the double line-to-neutral short-circuit torque provided the ratio X_q''/X_d'' is less than 3. The double line-to-neutral short-circuit torque will exceed the line-to-line short-circuit torque if X_q''/X_d'' is greater than 3. However, this ratio is less than 3 for commercial generators, so that the line-to-line short-circuit torque will normally exceed the double line-to-neutral short-circuit torque.

As a rule, the line-to-line short-circuit torque will thus exceed all other types of short-circuit torques.

Relative Values of Faulty Synchronizing Torques

Faulty 3-phase synchronizing occurs when the machine is connected to the system out of phase through a 3-pole circuit breaker. Faulty 1-phase synchronizing occurs when the machine is connected to the system out of phase, and only two poles of the 3-pole circuit breaker are closed.

1. For turboalternators, taking $X_2=X_d''$ approximately, Table I shows that the maximum single-phase faulty synchronizing torque will always exceed the 3-phase faulty synchronizing torque by about 8%.

2. For salient pole machines, taking $X_2=1/2(X_d''+X_q'')$ it can be shown that the single-phase synchronizing torque cannot exceed the 3-phase synchronizing torque by more than 8%, since X_2 is greater than X_d''. The single-phase torque will equal the 3-phase torque, when the ratio $X_q''/X_d''=1.33$ with the external system reactance $X_s=0$, and also when the ratio $X_q''/X_d''=1.65$ with the external system reactance $X_s=X_d''$. In large hydro stations the external reactance X_s does not usually exceed X_d'' and the ratio X_q''/X_d'' usually does not exceed 1.65.

As a rule, the single-phase faulty synchronizing torque for salient pole generators thus roughly equals the 3-phase faulty synchronizing torque.

It can be found by trial from the phasor diagrams that the angle of phase difference between the machine and the system which produces the highest faulty synchronizing torque is approximately 120 electrical degrees. It may be noted that a phase difference of 180 electrical degrees produces about 23% less peak torque than a phase difference of 120 electrical degrees, contrary to a fairly common misconception.

Time to Attain Peak Torque

The time taken from the instant of fault until the peak torque is reached can be obtained from the phasor diagrams used to derive the simplified equations. It is necessary only to find the displacement of the phasors at the instant of fault, and at the instant when the sum of the voltage times current products are a maximum.

SHORT-CIRCUIT TORQUES

For a 3-phase short circuit, the peak torque is reached at an instant corresponding to a displacement of 90 electrical degrees after the instant of short circuit, equivalent to 0.004 second at 60 cycles. For all other short circuits the peak torque will occur at an instant corresponding to a displacement of approximately 120 electrical degrees after the instant of short circuit, equivalent to 0.0055 second.

SYNCHRONIZING TORQUES

For 3-phase faulty synchronizing, the peak torque is reached at an instant corresponding to a displacement of approximately 120 electrical degrees after the instant of synchronizing, equivalent to 0.0055 second at 60 cycles. For single-phase faulty synchronizing the peak torque occurs at an instant corresponding to a displacement of approximately 150 electrical degrees after the instant of synchronizing, equivalent to 0.007 second at 60 cycles.

Relative Severity of Short-Circuit Faults and Out-of-Step Synchronizing

The question often arises whether out-of-step synchronizing will produce higher torques than will short-circuit faults.

THREE-FAULT FAULTY SYNCHRONIZING

A line-to-line short circuit usually produces the highest short-circuit torque. From Table I it can be seen that the 3-phase faulty synchronizing torque will exceed the line-to-line short-circuit torque, provided the connected system reactance X_s is smaller than the generator negative-sequence reactance X_2.

The connected system reactance X_s is the combined parallel reactance of all other generators on the same bus, and of the transmission circuits. In the case of unit-connected generators, X_s is the reactance of the unit transformer plus the combined parallel reactance of all other generator-transformer units, and of the transmission circuits.

In stations with generators on a common bus, and in most large unit-connected hydro stations, the connected system reactance X_s is smaller than the generator negative-sequence reactance X_2. Three-phase faulty synchronizing will then produce more severe torques than any short-circuit conditions.

However, in some unit-connected steam stations, having relatively high-voltage and high-reactance unit transformers, the system reactance X_s is greater than the generator negative-sequence reactance X_2. A line-to-line short circuit will then produce higher torques than 3-phase faulty synchronizing.

SINGLE-PHASE FAULTY SYNCHRONIZING

For turboalternators, the single-phase faulty synchronizing torque exceeds the 3-phase synchronizing torque by 8%. For salient pole machines the two torques are roughly equal. Since the 3-phase faulty synchronizing torque is often higher than any short-circuit torque, the single-phase faulty synchronizing torque will frequently exceed any short-circuit torque.

Out-of-step synchronizing is thus frequently more dangerous than short-circuit faults. It may be noted that out-of-step synchronizing is also much more likely to occur in operation than short circuits at the generator terminals. The danger of out-of-step synchronizing may be positively prevented by means of lock-out synchronizing relays, and in this case the foundations need only be designed to withstand the line-to-line short-circuit torque.

Summary

Summarizing the foregoing analysis, generator foundations can be designed on the following practical basis:

1. The reactions on the foundations oscillate in the directions shown in Fig. 1, and constitute severe reversing live loads on the concrete.
2. The assumption that all the generator air-gap torque is transferred to the sole plates introduces a factor of safety.
3. The magnitude of the maximum air-gap torque can be estimated rapidly by means of the simplified equations which are given in Table I.
4. A line-to-line short circuit usually produces the highest short-circuit torque.
5. The single-phase faulty synchronizing torque very roughly equals the 3-phase faulty synchronizing torque. The highest faulty synchronizing torque will occur when the machine is connected approximately 120 electrical degrees out of phase with the system. Out-of-step synchronizing is frequently more dangerous than any short circuit.
6. The peak air-gap torque is attained in approximately 0.004 to 0.007 second after the instant of short circuit or faulty synchronizing.

Appendix I. Effect of Saliency

The simplified equations include the effect of that part of the second harmonic torque, which is caused by the interaction of the rotating field due to the negative-sequence armature currents with the fundamental component of the rotor field. They do not include that part of the second harmonic torque which is due to saliency alone.

This is perfectly in order for turboalternators which have negligible saliency. However, for water-wheel generators, the effect of saliency can theoretically be approximated by multiplying the simplified equations in Table I, by a *K* factor, depending on the degree of saliency. In Fig. 2 the value of the *K* factor has been plotted for the important case of a line-to-line short circuit, for values of X_q''/X_d'' up to 1.6. This should cover most practical cases as this ratio is usually below 1.6 for large salient pole generators.

The value of the *K* factor was found by determining the effect of increasing the second harmonic torque by the ratio $2X_q''-X_d''/2(X_q''+X_2)$, as derived by Nickle, Pierce, and Henderson.[5]

Appendix II. Line-to-Line Short-Circuit Torque

Fig. 3 shows the phasor diagrams at the instant of short circuit and at maximum torque. Taking scalar magnitudes of the phasors, the maximum values are

$$E_m=\sqrt{2}E \tag{1}$$

$$I_1=I_2=\frac{E_m}{X_d''+X_2} \tag{2}$$

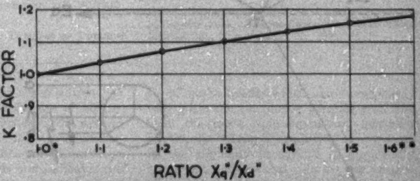

Fig. 2. Theoretical effect of saliency on line-to-line short circuit torque

* TURBOALTERNATORS
**PRACTICAL MACHINES USUALLY HAVE RATIOS BELOW 1·6

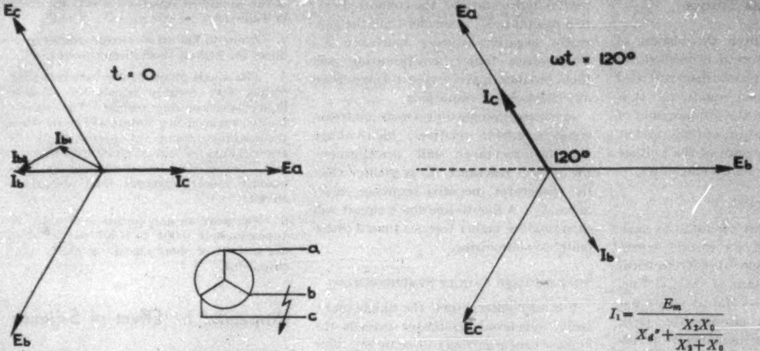

Fig. 3. Line-to-line short circuit

The angle between I_1 and I_2 is 60 degrees and combining them phasorially, the magnitude of phase current is

$$I_b = I_c = \frac{\sqrt{3}E_m}{X_d''+X_2} \tag{3}$$

At the instant of short circuit, the d-c components cancel the alternating components, hence the instantaneous value of the d-c component

$$i_b = I_b \tag{4}$$

$$i_c = -I_b \tag{5}$$

The peak torque occurs 120 degrees later, when alternating components have instantaneous values

$$i_b = \frac{I_b}{2} \text{ and } e_b = E_m \tag{6}$$

$$i_c = -\frac{I_b}{2} \text{ and } e_c = -\frac{E_m}{2} \tag{7}$$

Hence total currents

$$i_b = \frac{3I_b}{2} \tag{8}$$

$$i_c = -\frac{3I_b}{2} \tag{9}$$

The per-unit power is equal to the per-unit torque at synchronous speed, rated kva, and rated voltage

$$T = \frac{1}{3}(i_ae_a + i_be_b + i_ce_c) \tag{10}$$

which reduces to

$$\frac{3\sqrt{3}}{2}\frac{E^2}{X_d''+X_2} \tag{11}$$

The torque due to line-to-neutral, and 3-phase short circuits can be similarly derived.

Appendix III. Double Line-to-Neutral Fault

Fig. 4 shows the phasor diagrams for a double line-to-neutral fault. The scalar magnitudes of maximum positive sequence current

$$I_1 = \frac{E_m}{X_d'' + \frac{X_2X_0}{X_2+X_0}} \tag{12}$$

of maximum negative sequence current

$$I_2 = I_1\frac{X_0}{X_2+X_0} \tag{13}$$

and of maximum zero sequence current

$$I_0 = I_1\frac{X_2}{X_2+X_0} \tag{14}$$

At the instant of short circuit, the d-c components cancel the alternating components, hence instantaneous value of the d-c component

$$i_b = +\sqrt{\frac{3}{2}}(I_{b_1}+I_{b_2}) \tag{15}$$

$$i_c = -\sqrt{\frac{3}{2}}(I_{c_1}+I_{c_2}) \tag{16}$$

The peak torque occurs approximately 120 degrees later, when the instantaneous values of alternating components

$$i_b = \sqrt{\frac{3}{2}}(I_{b_2}-I_{b_0}) \text{ and } e_b = E_m \tag{17}$$

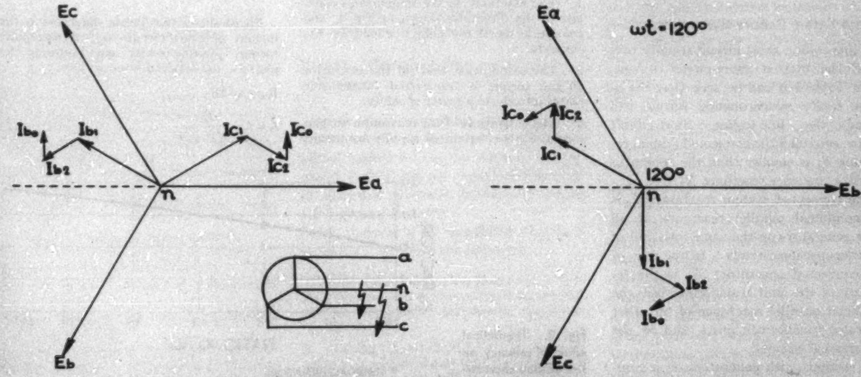

Fig. 4. Double-line-to-neutral short circuit

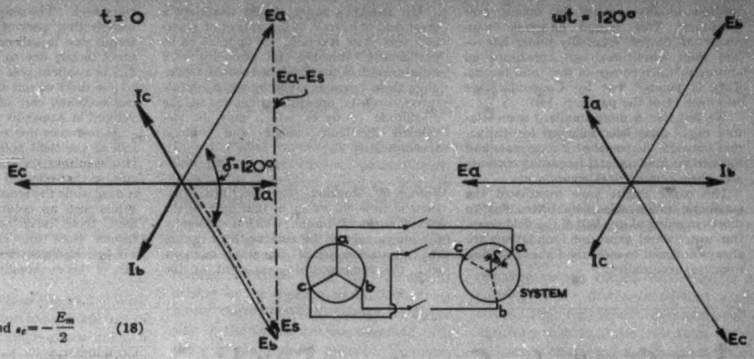

Fig. 5. Three-phase faulty synchronizing

$$i_c=-\sqrt{\frac{3}{2}}(I_{c_1}+I_{c0})\text{ and }e_c=-\frac{E_m}{2} \qquad (18)$$

Hence, total currents

$$i_b=\sqrt{\frac{3}{2}}(I_{b_1}+2I_{b_2}-I_{b_0}) \qquad (19)$$

$$i_c=-\sqrt{\frac{3}{2}}(2I_{c_1}+I_{c_2}+I_{c_0}) \qquad (20)$$

Per unit power and per unit torque is therefore

$$T=\frac{1}{3}(i_ae_a+i_be_b+i_ce_c) \qquad (21)$$

$$=\frac{\sqrt{3}E_m}{2\times 3}\left(2I_1+\frac{5}{2}I_2-\frac{I_0}{2}\right) \qquad (22)$$

And this reduces to

$$T=\sqrt{\frac{3}{2}}\times\frac{E^2}{X_d''+\dfrac{X_2X_0}{X_2+X_0}}\left(\frac{X_2+3X_0}{X_2+X_0}\right) \qquad (23)$$

Appendix IV. Three-Phase Faulty Synchronizing Torque

Fig. 5 shows the phasor diagrams for 3-phase faulty synchronizing, when the machine is 120 electrical degrees out of phase with the system. The scalar magnitude of maximum phase currents

$$I_a=I_b=I_c=\frac{\sqrt{3}E_m}{X_d''+X_s} \qquad (24)$$

At the instant of synchronizing, the d-c components cancel the alternating components, and their instantaneous values are

$$i_a=-I_a \qquad (25)$$

$$i_b=\frac{I_a}{2} \qquad (26)$$

$$i_c=\frac{I_a}{2} \qquad (27)$$

The maximum torque occurs 120 degrees later, when the alternating components have instantaneous values

$$i_a=-\frac{I_a}{2}\text{ and }e_a=-E_m \qquad (28)$$

$$i_b=I_a\text{ and }e_b=\frac{E_m}{2} \qquad (29)$$

$$i_c=-\frac{I_a}{2}\text{ and }e_c=\frac{E_m}{2} \qquad (30)$$

Hence total current

$$i_a=-\frac{3I_a}{2} \qquad (31)$$

$$i_b=\frac{3I_a}{2} \qquad (32)$$

$$i_c=0 \qquad (33)$$

Per-unit power and per-unit torque is therefore

$$T=\frac{1}{3}(e_ai_a+e_bi_b+e_ci_c) \qquad (34)$$

which reduces to

$$\frac{3\sqrt{3}}{2}\,\frac{E^2}{X_d''+X_s} \qquad (35)$$

The torque due to faulty single-phase synchronizing can be similarly derived.

Discussion

P. L. Dandeno and **K. R. Knights** (The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada): Prior papers have provided complicated equations for calculating maximum torques due to various short-circuit and faulty synchronizing conditions. Their complication has no doubt contributed to the use of certain rules of thumb now in existence, the general applicability of which are questionable. The author's one additional assumption simplifies these equations and indicates the relative magnitude of various fault torques.

It is rather remarkable, at first glance, to find that the author's method of analysis gives rise to results which agree reasonably well with the maximum torques resulting from the more rigid equations presented previously. The assumption referred to in the previous paragraph is apparently borne out in a general way by the results. The author also states that he neglects harmonics due to saliency. How does he effectively account for the second harmonic torques usually present in salient pole machines? This second harmonic component of torque, especially under line-to-line fault conditions, can constitute an appreciable percentage of the total torque. This is pointed out by Concordia (see reference 14 of the paper, p. 140).

We feel that a more standard nomenclature might have been followed for distinction between the so-called d-c currents and the various fundamental frequency currents and their symmetrical components.

The paper might have mentioned the maximum radial sole plate forces due to short-circuiting of one-half of the field poles. Our water-wheel generator foundations are always designed to meet the forces resulting from this eventuality.

Mr. Ruskin's paper should stimulate a great deal of interest in the subject of generator sole plate reaction. It appears to be particularly valuable in providing the utilities with a practical method of evaluating these forces as given by the manufacturers, and in drawing attention to the magnitude of forces which may be developed by faulty single- and 3-phase synchronizing.

Vernon W. Ruskin: The simplified equations include the effect of that part of the second harmonic torque, which is caused by the interaction of the rotating field due to the negative-sequence armature currents with the fundamental component of the rotor field. The simplified equations do not include that part of the second harmonic torque due to saliency, which is the reluctance torque due to the trapped armature flux in a salient pole machine.[5] For a line-to-line short circuit this part of the torque can be taken care of by the *K* factor developed in Appendix I.

As to forces due to short circuit of one-half of the field poles, this event requires two simultaneous grounds in the rotor circuit, so that one-half of the rotor periphery is dead while the remainder is still energized. While such an occurrence is very uncommon, there have been isolated cases of trouble from this cause. The discussers wisely design generator foundations to take care of this eventuality.

Test Circuits for Capacitance Switching Devices

K. G. DARROW

R. B. SHORES
MEMBER AIEE

THE energization and de-energization of capacitive kilovolt-amperes (kva) impose special switching conditions on switching devices. For example, these switching devices might be circuit breakers, disconnect switches, or load break switches which are primarily intended for resistive or inductive current interruption. Switching tests must be performed to determine the switching device rating for switching capacitive kva. As discussed in a companion paper,[1] dependent upon the predominant system component involved such as a capacitor bank, cable, or overhead line, the imposed conditions can be different and thereby result in different capacitive kva capabilities for the switching device. For conciseness, the various switching devices will be referred to hereafter simply as devices.

In the testing of switchgear, particularly at the higher voltages, laboratory facilities are usually such that only one phase of a device is tested to determine its ability to interrupt capacitive currents.[2] Consequently, it is required that the single-phase test circuit should subject the test component of the device to the same equivalent conditions as it would encounter in an actual 3-phase installation. Voltages and currents resulting from the single-phase test circuit must be interpreted relative to the 3-phase circuit.

This paper describes, defines, and demonstrates the equivalency of single-phase test circuits and test voltages and of the corresponding 3-phase kva being switched in terms of a capacitor bank, cable, or overhead line. The test circuit is defined as that which is observed from the device terminals and hence is independent of the configuration of the device itself. The paper is based in part on the results presented in a companion paper on system requirements of switchgear in switching capacitive kva.[1]

Conclusions

1. Single-phase circuits which impose exactly the same duty on any one pole of the switching device as the 3-phase circuit can be developed for most cases involving capacitance switching. These circuits may not be practical for laboratory testing of switching devices.
2. Modifications of the exact single-phase equivalent circuits can be made which result in circuits which are practical for laboratory testing. In some cases, these modified circuits do not duplicate the 3-phase conditions.
3. For any known condition of system or capacitance configuration, practical single-phase circuits suitable for laboratory testing can be synthesized even though an exact equivalent circuit cannot be derived. These synthesized circuits may only approximate the conditions of the 3-phase circuit.

Test Circuits

It is desirable to use as simple a test circuit as possible consistent with the results which are required. The use of a simple circuit for testing the capacitance switching ability of devices in the testing laboratories leads to minimizing of the test equipment, convenience in metering, and a reduction of the setup time and test samples. Usually devices are tested in the laboratories for their capacitance switching ability on a single-phase circuit

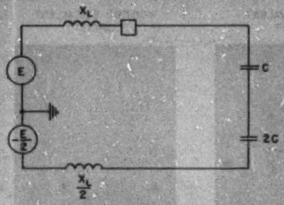

Fig. 2. Exact equivalent circuit to subject one pole of a switching device to the same duty as the 3-phase circuit of Fig. 1

with a capacitor bank as the load. With a given size capacitor bank made up of a given number of single-phase units, a device can be tested single phase to a higher equivalent 3-phase kilovar than can be tested three phase.

A circuit breaker installed on a power system may have to switch a capacitor bank, cable, or overhead line under various conditions of grounding. It is necessary to relate these actual system conditions, which are three phase, to any single-phase circuit which is used in the laboratory. The single-phase circuit should be such that it applies the same voltage across the device contacts as does the 3-phase circuit. In addition, a relationship must be established between overvoltages to ground due to restrikes in the 3-phase circuit and overvoltage to ground in the single-phase test circuit. In the following sections, the single-phase test circuits will be derived and discussed for each of the 3-phase capacitive circuit conditions under which a device may be called upon to operate.

Test Circuits Representing Unfaulted Conditions—First Pole Opening

GROUNDED CAPACITOR BANK AND SHIELDED CABLE

The simplest 3-phase condition of capacitance is the completely grounded system in which the power source neutral and the neutral of the capacitance are both tied together and grounded through connections of zero impedance. These conditions are met if the source is solidly grounded and the load is a grounded capacitor bank or a shielded cable. The three phases of the circuit are independent of each other and a single-phase circuit to test one pole of a device would consist of a duplication of one phase of the 3-phase circuit.

UNGROUNDED CAPACITOR BANKS

The capacitor bank connection most commonly found in practice is that of Fig. 1. This circuit includes an ungrounded capacitor bank and a grounded source. One pole of a device may interrupt more than 1/2 cycle before either of the other poles. A single-phase circuit may be derived which subjects one pole of a device to exactly the same conditions that it would experience if it were the first pole to open in this 3-phase circuit. This exact equivalent circuit is shown in Fig. 2 and is derived in Appendix I.

The circuit of Fig. 2 is an exact equivalent circuit in that the conditions imposed across the device terminals are in every respect identical with the conditions arising in the 3-phase circuit. Furthermore, the voltages to ground on either side of the switch are also identical with those in the 3-phase system. However, as a practical circuit for testing switching devices in the laboratories, the equivalent circuit of Fig. 2 is not convenient because of difficulties in metering, obtaining the correct voltage tap, and dividing the reactance properly.

Since the ground point in Fig. 2 is only a point of voltage reference, it may be moved without influencing the circuit; i.e., because there is only one ground point in the circuit, no current can flow in the ground connection and it may be located at any point in the circuit. As a convenience, then, ground may be moved from the 1/3 voltage tap to one terminal of the single-phase source transformer and the modified equivalent circuit of Fig. 3 results.

The equivalence of the two circuits, Figs. 2 and 3, to the actual circuit of Fig. 1 is demonstrated in the oscillograms of Fig. 4. Fig. 4(A) shows the voltages to ground on each side of the device and the recovery voltage across the device for a clearing of the first pole without a restrike. Fig. 4(B) shows these same voltages for a restrike at the crest value of the recovery voltage and a subsequent clearing at the first natural frequency current zero. Fig. 4(C) shows the voltage across the switched phase capacitor in the actual circuit and in the exact equivalent circuit for an interruption with and without one restrike. It can be seen in these oscillograms that the recovery voltage across the device is the same in all three circuits.

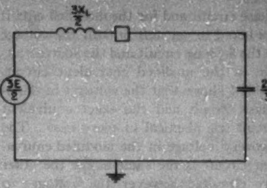

Fig. 3. Modified equivalent circuit for ungrounded capacitor banks

The voltages to ground in the circuits are different but may be interpreted by use of Table I. In Table I the voltages to ground on both sides of the device, the recovery voltage, and the voltage across the switched phase capacitor are listed for the three circuits at different times following the first interruption. These voltages are for a restrike at the crest of the recovery voltage which is interrupted at the first natural frequency current zero in a circuit with no damping. The voltages for the 3-phase circuit and the exact equivalent circuit are given in per unit of the line-to-neutral voltage in the 3-

Table I. Comparison of Theoretical Voltages* in Actual Circuit and Single-Phase Circuits for Switching an Ungrounded Capacitor Bank

Across switched phase capacitor	−1.5 (−1.0)	−1.5 (−1.0)	−1.5 (−1.0)	+4.5 (+3.0)	+4.5 (+3.0)	+4.5 (+3.0)

*Voltages are in per unit of line-to-neutral voltage in the 3-phase circuit. Figures in parentheses are the voltages in the modified equivalent circuit in per unit of the source voltage in the modified circuit.

phase circuit and for the modified circuit are listed in per unit of both the voltage in the 3-phase circuit and the source voltage in the modified equivalent circuit. Table I shows that the voltages in the 3-phase circuit and the exact equivalent circuit are identical in every case. The recovery voltage in the modified equivalent circuit is the same as for the other two circuits; however, the voltages to ground on the source side of the switch are seen to be $1^1/_2$ times the corresponding voltages in the actual and exact equivalent circuits when expressed in the same per-unit system. The voltages to ground on the source in the modified circuit in per unit of the source voltage of the modified circuit are seen to be the same numbers as the corresponding voltages in the other circuits in per unit of the line-to-neutral voltage in the 3-phase circuit. It is also seen in Table I that the voltage to ground on the capacitor in the modified circuit corresponds to the voltages across the switched phase capacitor in the actual 3-phase circuit and in the exact equivalent circuits when they are expressed relative to their own source voltage. The voltages to ground on the capacitor are the same in per unit in all three circuits only during the periods in which current flows in the switch.

The modified equivalent circuit, then, results in the same recovery voltage across the device and the same current in the device as does the actual 3-phase circuit. The voltages to ground on the source side of the device in the modified circuit and the 3-phase circuit are the same in per unit when they are expressed relative to their own source voltages; and the voltage to ground on the capacitor in the modified circuit and the voltage across the switched phase capacitor in the 3-phase circuit are the same when they are expressed in their respective per-unit systems.

Transmission Line and Unshielded Cable

An unloaded transmission line acts like a capacitive circuit in which some of the capacitance is grounded and some of the capacitance is ungrounded. It may be represented by the circuit shown in Fig. 5, which assumes that the source is grounded in such a manner that it has an $X_0/X_1=1.0$ and that the distributed inductance of the transmission line may be neglected.

If it is assumed again, as previously, that one device pole can open more than 1/2 cycle ahead of the other two, a single-phase circuit may be derived that will impose the exact conditions on one pole that the 3-phase circuit of Fig. 5 imposes on the first pole to clear. This single-phase circuit is shown in Fig. 6. The similarity between Figs. 6 and 2 is evident. Inspection reveals that Fig. 6 would not be convenient to use as a laboratory test circuit.

Fig. 6 may be further reduced, as is proved in Appendix II, to the modified equivalent of circuit of Fig. 7. It is seen that Fig. 7 is a simple single-phase circuit with a source inductance and a capacitance to be switched; however, the magnitudes of both the source voltage and the capacitance to be switched are primarily a function of the relationship of the portion of the capacitance that is grounded and the portion of the capacitance that is ungrounded. This may be expressed in terms of the positive-sequence and zero-sequence capacitance in the circuit.

The source voltage to be used in the modified equivalent circuit of Fig. 7 is plotted in Fig. 8 as a function of the

Fig. 7 (above right). Modified equivalent circuit for generalized capacitance circuit

ratio of the positive-sequence capacitance C_1 to the zero-sequence capacitance C_0 for an assumed circuit regulation X_L/X_{C1} of zero (a regulation of 0.10 makes less than 1-per-cent difference in the equivalent source voltage). It is seen that a source voltage of 1.0 per unit of the line-to-neutral voltage in the 3-phase circuit is required for a $C_1/C_0=1.0$ which is a circuit in which all capacitance is grounded. A source voltage of 1.5 per unit arises in a circuit for which $C_1/C_0=\infty$; i.e., all capacitance ungrounded. This confirms the circuits previously derived for the totally grounded or ungrounded capacitances. Transmission lines and unshielded cables generally have a C_1/C_0 ratio of from 1.6 to 2.0 requiring an equivalent circuit test voltage of from 1.14 per unit to 1.2 per unit.

A comparison of the results obtained by using the equivalent circuits of Figs. 6 and 7 with those resulting from the actual circuit of Fig. 5 may be seen in the oscillograms of Fig. 9. Fig. 9(A) shows a clearing without a restrike and Fig. 9(B) shows a restrike of 1/2 cycle of natural frequency duration occurring at the crest of the recovery voltage; in these figures, the voltages across the switch and to ground on either side of the switch are shown. Fig. 9(C) shows the voltages across the switched phase capacitor in the actual circuit and in the exact single-phase circuit.

The voltages resulting from these three circuits are given at various times during an opening operation in Table II. The oscillograms of Fig. 9 and the voltages listed in Table II indicate that the modified equivalent circuit does not always duplicate the conditions of the exact equivalent circuit and the actual 3-phase circuit. The modified equivalent circuit only duplicates the recovery voltage across the device prior to a restrike. If a restrike occurs, and the device clears again at a natural frequency current zero, the subsequent recovery voltage across the device is more severe in the modified circuit than in the actual or exact equivalent circuit. This is due to the fact that the latter two circuits are double-frequency circuits whereas only a single natural frequency is possible in the modified circuit. The voltages to ground in the modified circuit are not related to the corresponding voltages to ground in the other circuits.

The modified equivalent circuit of Fig. 7, then, may be used to subject one pole of a device to the same conditions that it would encounter if it were the first pole to open when switching an unloaded transmission line with complete accuracy up to the instant at which a restrike occurs. Following this instant, the conditions are only approximately the same.

Effect of Source Grounding

Up to this point this discussion has been concerned with the capacitance conditions that may be encountered and has been restricted to power sources grounded in such a manner that $X_0/X_1=1.0$ for the source. A variation in grounding impedance can only have an effect

if there is another ground point in the system, since, for any circuit having only the source grounded, no current can flow in the neutral impedance of the source and it must be at ground potential at all times. Therefore, the method of source grounding is of interest only in the cases of grounded capacitor banks, cables, and overhead lines if no faults are involved. A circuit involving a grounded capacitor bank or a shielded cable and a source with variable grounding impedance is shown in Fig. 10. Application of Thévenin's theorem results in the single-phase equivalent circuit for the first pole to open that is shown in Fig. 11. It will be noted in Fig. 11 that the source voltage for the equivalent circuit will be a very large number for certain values of the grounding impedance. The reason for this can be found by referring to Fig. 10 where it is seen that with one phase open a path through the ground involving the source impedance, the grounding impedance, and the capacitance in series may result in a resonant circuit if the grounding impedance is a large value of reactance. If the grounding impedance is largely resistive, these overvoltages cannot occur and the highest equivalent source voltage is 1.5 per unit when the grounding resistance is infinite.

The same situation is true when switching transmission lines. A high value of X_0/X_1 ratio for the source may require a very high equivalent source voltage in the single-phase equivalent circuit.

If the grounding condition is such that it meets the requirements of type-B grounding ($X_0/X_1 \leq 3.0$, $R_0/X_1 \leq 1.0$), the effect of the ground impedance is of little consequence, as is seen in Fig. 12, and the equivalent circuits previously described may be used. If the source is ungrounded the grounding condition of the capacitance network has no effect on the duty imposed on the device. Since any grounding associated with the capacitance is the only ground point in the circuit, it is only a point of voltage reference and no current may flow in it. Therefore the device duty is exactly the same as would be encountered when an ungrounded bank is switched. The modified equivalent circuit of Fig. 3 duplicates the conditions for this case. For grounding conditions not described here, no generalities may be made. The duty will depend on these grounding conditions if the capacitance is grounded, and the source grounding conditions would have to be known before an equivalent circuit could be used for testing.

Test Circuits Representing Unfaulted Conditions—Second Pole Opening

Grounded and Ungrounded Capacitor Banks

If a grounded capacitor bank is being switched from a grounded source of power, the three phases are independent of each other. Therefore, the first, second, or last poles of the device to clear would experience the same conditions. The modified equivalent circuit is in this case an exact equivalent and represents a test of any pole.

When switching an ungrounded capacitor bank, it is shown in the companion paper[1] that higher voltages can exist across the second pole to clear than across the first pole. It should be remembered that this represents a condition of mechanical delay in one of the two last phases since current must be interrupted in both of these phases of the device simultaneously. This is because they are in series across the line-to-line voltage.

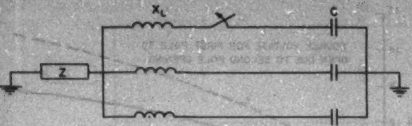

Fig. 10 (left). Grounded capacitance bank switched from impedance grounded source

Fig. 11 (left). Exact equivalent circuit for Fig. 10

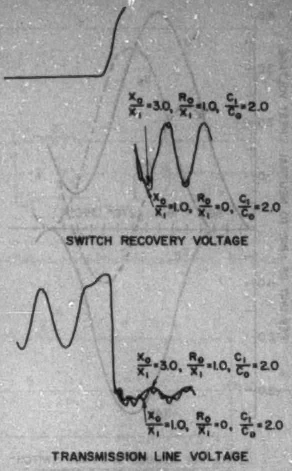

Fig. 12 (right). Effect of increasing source X_0/X_1 from 1.0 to 3.0 and source R_0/X_1 from zero to 1.0 on voltages when switching a transmission line. One restrike at crest of recovery voltage

The recovery voltage across the first phase to clear as a result of the second phase clearing 1/4 cycle later is shown in Fig. 13. It is seen that this recovery voltage reaches a crest value of 4.1 per unit which occurs 210 degrees after the current extinction in the phase in question and it reaches this magnitude only if the next phase to clear is the phase which lags the first phase to open by 120 degrees. That is, the opening phase rotation must be assumed to be phases *A-B-C* and not phases *A-C-B*.

Because of the nature of the circuit in which two phases are being opened, no exact single-phase equivalent circuit involving one switching operation is possible. However, a modified circuit may be synthesized. The recovery voltage curve of Fig. 13 is very nearly of the form (1-cos θ) for the first half-cycle. This is the form resulting from the modified test circuit. But since it takes 210 degrees for the recovery voltage to reach crest value, a lower frequency (51.5 cycles) would have to be used in the test circuit. The impedances have to be adjusted so that the proper value of current will flow. In other words, one pole of a device may be subjected to the conditions it would encounter if it were the first pole to open when switching an ungrounded capacitor bank and another pole had not yet opened mechanically. The modified test circuit may be used with a source voltage of 2.05 per unit, with a test frequency of 51.5 cycles, a source inductance 2.4 times that of the 3-phase circuit, and a capacitance equal to 0.6 times that of one phase of the 3-phase circuit.

TRANSMISSION LINE

As for the previous case, the opening of the second pole when switching a transmission line may result in a higher voltage across the first pole that opened. The higher voltage will occur during the first half-cycle of recovery voltage across the first pole only if *B* phase is the second to open. Since a current zero occurs in *C* phase before a current zero appears in *B* phase, the *C* phase pole must skip a current zero, or not yet be mechanically open, for the *A* phase recovery voltage to be increased.

Again, an exact equivalent circuit is not obtainable but a modified test circuit can be synthesized from the voltages that were measured in a 3-phase circuit. The equivalent source voltages for the modified test circuit are shown in Fig. 14 in comparison with those for the first phase to clear when no other phases are opening. These values were obtained on the transient network analyzer when switching a transmission line from a source that was solidly grounded. In the range in which most transmission lines fall, the source voltages to represent second pole opening are about 8 per cent more than those due to the first pole opening. These voltages do not appear until more than 1/2 cycle after current extinction in the first phase to clear.

EFFECTS OF SOURCE GROUNDING CONDITIONS

The equivalent circuits given above are for 3-phase circuits grounded in such a manner that the X_0/X_1 ratio of the source is unity. If the ground is increased to the limits described by type-*B* grounding, no appreciable difference will result in the equivalent circuits derived. If the source is ungrounded, the device duty is the same as for the case of ungrounded capacitance with a grounded source. This is true re-

Table II. Comparison of Theoretical Voltages* in Actual Circuit and Single-Phase Circuits for Switching Transmission Line

gardless of the capacitance grounding conditions. For systems not grounded in accordance with the requirements given here, the equivalent circuits for second pole opening when switching grounded capacitive circuits depend on the manner of source grounding and no generalizations can be made.

Faulted Circuits—First Pole Opening

Grounded Capacitor Banks

If the first pole to clear is assumed to be in an unfaulted phase when switching a grounded capacitor bank, as shown in Fig. 15(A), this pole may be tested in the exact equivalent circuit of Fig. 15(B). The single-phase source voltage of the exact equivalent circuit depends on the source grounding and, for the case shown in Fig. 15(B) with type-*B* grounding, the source voltage is 135 per cent of the leg voltage of the 3-phase circuit. Regardless of the manner of source grounding, the single-phase source voltage cannot exceed line-to-line voltage of the 3-phase circuit.

This circuit can be reduced to a modified equivalent circuit by combining the load impedances. For this case, the modified circuit would consist of a capacitance equal to the per-phase capacitance of the 3-phase circuit and a source inductive reactance equal to 142 per cent of the positive-sequence reactance of the source in the 3-phase circuit. The modified equivalent circuit is exact prior to a restrike and approximately correct thereafter since the modified circuit only has one natural frequency of oscillation.

Ungrounded Capacitor Banks

Two fault conditions involving ungrounded capacitor banks are of interest. If the source is grounded, a line-to-ground fault at the capacitor bank results in abnormal capacitive switching duty on the unfaulted phases of the device. A failure of a portion or all of the capacitors in one phase also changes the duty on the device.

An exact equivalent circuit to test the first pole of a device to interrupt when switching an ungrounded capacitance with a line-to-ground fault on one phase may be derived if it is assumed that this pole is in an unfaulted phase, as shown in Fig. 16(A). The source voltage in the exact equivalent circuit depends on the manner of grounding of the source. In the circuit of Fig. 16(B) the grounding impedance on the source side of the switch is such that viewed from the switch location the circuit has type-*B* grounding. The resultant source voltage in the exact equivalent circuit for this condition is 130 per cent of the leg voltage of the 3-phase circuit. The source voltage of the single-phase circuit will not exceed line-to-line voltage of the 3-phase

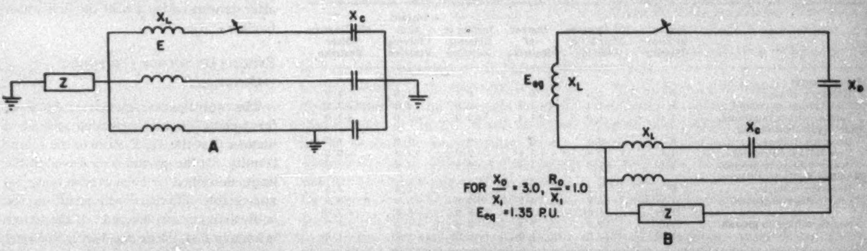

Fig. 15. A—First pole to open in an unfaulted phase when switching a grounded capacitance with a line-to-ground fault on one phase. B—Exact equivalent circuit for the 3-phase circuit of A

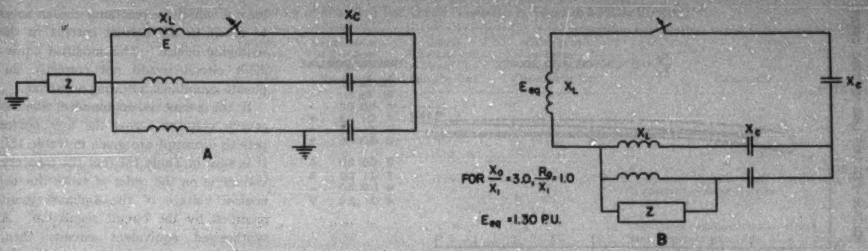

Fig. 16. A—First pole to open in an unfaulted phase when switching an ungrounded capacitance with a line-to-ground fault on one phase. B—Exact equivalent circuit for the 3-phase circuit of A

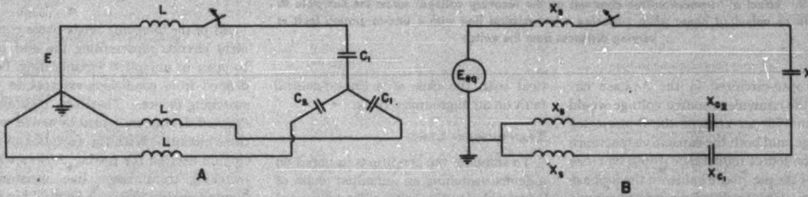

Fig. 17. A—First pole to open in a normal phase when switching an ungrounded capacitance bank in which the capacitance in one phase is more or less than that in the other two phases. B—Exact equivalent circuit for 3-phase circuit of A. Note: E_{eq} is given in Fig. 18

circuit regardless of the grounding of the source. The impedance network on the load side of the switch in this exact equivalent circuit may be combined to result in a modified equivalent circuit. This results in an equivalent load which is a capacitance whose reactance is 146 per cent of the capacitive reactance per phase of the 3-phase bank. This will result in the correct current through the switch and a recovery voltage across the switching device that is identical to that arising in the 3-phase circuit up to the time that a restrike occurs. The modified equivalent circuit is a single-frequency circuit whereas the 3-phase circuit has two natural frequencies. During and following a restrike the modified circuit is only approximately correct. It should be noted that the current and the recovery voltage across the device are less severe when there is a fault on one phase than when switching the circuit unfaulted.

UNGROUNDED CAPACITOR BANK—UNBALANCED CAPACITANCE

If a portion of the capacitance is lost in one phase of a capacitor bank, unbalancing the capacitance in the phases, the duty on the first pole of the switch to interrupt current is changed from the balanced case. Because of the series-parallel arrangement of capacitor units found in high-voltage capacitor banks, a loss of capacitor units or fuse blowing may increase or decrease the capacitive reactance.

The first pole to open in Fig. 17(A) experiences the same duty as the switch in the exact equivalent circuit of Fig. 17(B). The source voltage for the equivalent circuit of Fig. 17(B) is given in Fig. 18 as a function of the percentage of capacitive reactance unbalance and the unfaulted system regulation.

The exact equivalent circuit of Fig. 17(B) may be reduced to a modified equivalent circuit if the percentage of capacitive reactance unbalance is known. If the capacitance in one phase were short-circuited in the 3-phase circuit, the modified equivalent circuit would consist of a source voltage equal to the line-to-line voltage of the 3-phase circuit, a capacitance equal to the capacitance per phase of the 3-phase circuit, and a source inductance equal to twice the 3-phase circuit source inductance. If the capacitance

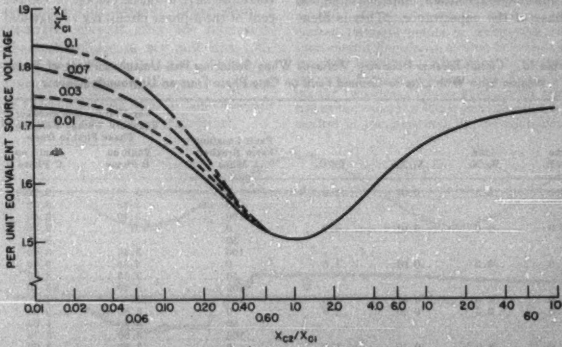

Fig. 18. Source voltages to be used in the equivalent circuit of Fig. 17(B) as a function of the capacitive reactance unbalance and the unfaulted circuit regulation

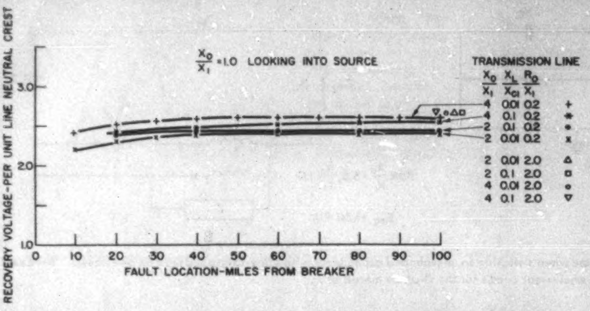

Fig. 19. Effect of transmission-line constants on the recovery voltages across the first pole to clear in an unfaulted phase when switching a transmission line with a line-to-ground fault at varying distances from the switch

were open-circuited in the 3-phase circuit, the equivalent source voltage would remain 173 per cent of the 3-phase leg voltage, and both the capacitive reactance and the source inductance would be twice that of the per-phase values of the 3-phase circuit. The modified equivalent circuit would be only approximate following a restrike because the modified circuit does not have the multiple natural frequencies present in the actual circuit.

UNGROUNDED SOURCE

If the source is ungrounded and the capacitance bank is ungrounded, the ground connection due to a line-to-ground fault has no effect on the duty on the first switch pole to interrupt. The modified equivalent circuit of Fig. 3 duplicates the duty on this switch pole under all conditions.

If the source is ungrounded, and the capacitance bank is grounded, a line-to-ground fault essentially short-circuits one phase of the capacitance. This is identical with the case of a line-to-neutral fault on an ungrounded bank.

TRANSMISSION LINES

To simulate the conditions imposed on a device switching an unfaulted phase of a transmission line with a line-to-ground fault on another phase, a circuit will have to be synthesized from the voltage conditions in the 3-phase circuit. Fig. 19 shows the crest of the recovery voltage across the first switch pole to interrupt when switching a transmission line with a line-to-ground fault on another phase at a location remote from the breaker. This information was obtained on the transient network analyzer and assumed a source that was solidly grounded ($X_0/X_1=1.0$). Fig. 19 indicates that the recovery voltage may be as high as 260 per cent of the line-to-neutral voltage of the unfaulted 3-phase circuit. The synthesized modified equivalent circuit should therefore have a source voltage of 130 per cent of the 3-phase circuit leg voltage and have a capacitive reactance chosen so as to result in the correct current in the switching device. This modified equivalent circuit would not correctly duplicate conditions following a restrike.

Table III. Circuit-Breaker Recovery Voltages When Switching First Unfaulted Phase of Transmission Line With Line-to-Ground Fault on One Phase From an Ungrounded Source

Line X_0/X_1	Line R_0/X_1	X_1/X_{c1}	C_1/C_0	Fault Location From Breaker, Miles	Per-Unit Crest of Breaker Recovery Voltage Unfaulted Phase First to Open: Fault on B Phase	Fault on C Phase
2.0	0.2	0.01	1.6	0	3.36	3.36
				50	3.38	3.38
				100	3.40	3.40
2.0	2.0	0.01	1.6	0		3.36
				50		3.38
				100	3.40	3.40
4.0	0.2	0.01	1.6	0	3.36	3.36
				50	3.38	3.38
				100	3.40	3.40
4.0	2.0	0.01	1.6	100	3.40	
4.0	2.0	0.10	1.6	0	3.80	3.60
				50	3.80	3.64
				100	3.80	3.70
4.0	2.0	0.10	1.6	0	3.80	3.60
				50	3.80	3.64
				100	3.80	3.70

If the source is ungrounded, the recovery voltages across the first device pole to interrupt are given in Table III. It is seen in Table III that the recovery voltage is on the order of twice line-to-neutral voltage of the 3-phase circuit modified by the circuit regulation. A synthesized equivalent circuit, then, should have a source voltage equal to the line-to-line voltage of the 3-phase circuit.

Effect of Shunting Resistors

All of the foregoing single-phase equivalent circuits representing the first pole to open in unfaulted circuits have been defined from conditions external to the switching device. Therefore, resistance-shunted devices may also be tested with these circuits. With the exception of the circuits derived for testing devices when switching transmission line, resistance-shunted devices may also be tested in the equivalent circuits simulating conditions arising from first pole opening when switching faulted circuits. It would not be correct to use the test circuits simulating second pole opening for resistance-shunted devices.

Summary of Results

Although exact equivalent single-phase test circuits have been derived, it is more practical to use a modified circuit for laboratory testing of capacitance switching devices. Table IV summarizes the parameters and conditions to be used in the modified test circuit for the various capacitance and grounding conditions that can be found in 3-phase circuits.

CALCULATION OF KILOVARS

The equivalent 3-phase kilovar of a single-phase capacitance switching test is calculated for unfaulted conditions as $\sqrt{3}$ (line-to-line kilovolt) (amperes test current). The line-to-line kilovolt is that on which the test voltage is based; e.g., maximum design voltage.

As an illustration, suppose single-phase tests are to be made on a 69-kv device to represent an ungrounded capacitor bank on an effectively grounded system. The maximum design voltage for the device is 72.5 kv, or 42 kv line-to-neutral. The single-phase test voltage is 1.5 (42) or 63 kv. If the test current is 160 amperes, the equivalent 3-phase kilovar is $\sqrt{3}$ (72.5) (160) or 20,000 kilovars.

Table IV. Summary of Modified Test Circuit Parameters in Terms of 3-Phase Circuit

	Voltage of 3-Phase Circuit, Per Unit	Capacitance of 3-Phase Circuit, Per Unit	Source Inductance of 3-Phase Circuit, Per Unit	Current of 3-Phase Unfaulted Circuit, Per Unit	Comments
Grounded Banks and Shielded Cables					
Grounded source					
No fault					
First pole	1.0	1.0	1.0	1.0	
Second pole	1.0	1.0	1.0	1.0	
Line-to-ground fault, type-B grounding					
First pole	1.35	1.0	1.42	1.42	equivalent circuit only approximately correct following restrike.
Ungrounded source					
No fault					
First pole	1.5	0.67	1.5	1.0	duplicates conditions across switch.
Second pole	2.0	0.57	2.4	1.0	test frequency should be 51.5 cycles, only approximate following restrike.
Line-to-ground fault					
First pole	1.73	1.0	2.0	1.94	only approximate following restrike.
Ungrounded Banks					
Grounded source					
No fault					
First pole	1.5	0.67	1.5	1.0	duplicates conditions across switch.
Second pole	2.0	0.57	2.4	1.0	approximate following restrike-test frequency of 51.5 cycles.
Line-to-ground, type-B grounding					
First pole	1.3	0.69	1.0	0.86	approximate following restrike.
Unbalanced capacitance					
Short circuit in one phase	1.73	1.0	2.0	1.94	
Open circuit in one phase	1.73	0.5	2.0	0.78	
Ungrounded source					
No fault					
First pole	1.5	0.67	1.5	1.0	duplicates conditions across switch.
Second pole	2.0	0.57	2.4	1.0	test frequency 51.5 cycles.
Line-to-ground fault					
First pole	1.5	0.67	1.5	1.0	duplicates conditions across switch.
Second pole	2.0	0.57	2.4	1.0	test frequency 51.5 cycles.
Unbalanced capacitance					
Short circuit in one phase	1.73	1.0	2.0	1.94	approximate following restrike.
Open circuit in one phase	1.73	0.5	2.0	0.78	
Transmission Line and Unshielded Cable					
Grounded source					
No fault					
First pole	1.2	$0.83C_1$	1.0	1.0	approximate following restrike.
Second pole	1.3	$0.77C_1$	1.0	1.0	
Line-to-ground, type-B grounding					
First pole	1.3	$1.0C_1$	1.42	1.42	
Ungrounded source					
No fault					
First pole	1.5	$0.67C_1$	1.5	1.0	duplicates conditions across switch.
Second pole	2.0	$0.57C_1$	2.4	1.0	approximate following restrike.
Line-to-ground fault					
First pole	1.73	$1.0C_1$	1.0	1.56	approximately duplicates conditions.

The application of devices on capacitor banks involves a further consideration. In the foregoing example, the device performance has been demonstrated for 20,000 kilovars, yet it might not be suitable for switching a capacitor bank with a 20,000-kilovar rating. Considering probable excess capacitance in the bank, possible harmonics, and operation at 10 per cent above nominal rated voltage, capacitor bank standards require their successful performance at 135 per cent of rated kilovar. As switching of a capacitor bank will normally be done when the voltage is high, the device should operate satisfactorily at 135 per cent of the nominal bank rating. Thus, the 20,000-kilovar device in the example, could be applied on a capacitor bank with a nominal rating of 20,000/1.35 or 14,800 kilovars.

Laboratory Tests

Capacitance switching tests in our Laboratory are normally made single phase using the circuit shown in Fig. 3. The device's performance over the range of currents up to its rating and at several values of tripping angle at each current value is determined. Fig. 20 shows one cathode-ray oscillogram of a high-voltage oil circuit breaker interrupting a capacitive current after one reignition. The test voltage in per unit was 1.43, based on maximum design voltage. Traces *A* and *B* are the voltages to ground on the source side and on the capacitor bank side of the breaker respectively.

Appendix I. Derivation of Equivalent Circuit

Thévenin's theorem states that any network may be represented between any two arbitrary terminals in the network by placing a generator whose voltage is equal to the open-circuit voltage between the desired terminal points in series with the short-circuit impedance as seen between the arbitrary terminals. Therefore, the 3-phase circuit of Fig. 1 may be simplified by replacing the two closed phases between the neutral of the capacitor bank and the grounded neutral of the generator by the equivalent

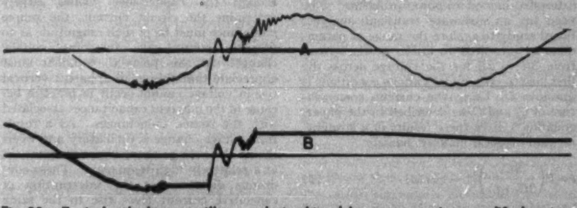

Fig. 20. Typical cathode-ray oscillogram obtained in a laboratory test using a modified equivalent circuit. Test voltage is 1.43 per unit

network given by application of Thévenin's theorem.

By breaking the 3-phase network at the neutral of the capacitor bank and looking back into the remaining two phases, the voltage between point N and ground may be determined as well as the short-circuit impedance between these two points. The voltage between point N and ground with the disconnected third phase as phase-angle reference is

$$V_n = E\left(\frac{\sin(\theta+120)+\sin(\theta-120)}{2}\right) = -0.5E\sin\theta$$

That is, the equivalent voltage behind the short-circuit impedance is equal to one-half of the phase voltage of the 3-phase circuit and is of opposite polarity to the unrepresented third phase. The short-circuit impedance is equal to the parallel impedance of two phases of the capacitor bank.

This discussion leads to the equivalent circuit of Fig. 2. Any trapped charges arising in the 3-phase circuit will appear properly in the equivalent circuit. From the equivalent circuit it may be seen that the ratio of the voltage due to the trapped charge to the source voltage is the same in either branch of the circuit proceeding from the neutral point to ground despite the time variation in the instantaneous value of the voltage sources. Consequently, whenever the switch is closed, the neutral of the capacitor bank must be at ground potential.

Since there can be no current flow in the ground connection, it serves only as a reference point for voltage measurements. The single-phase circuit may be grounded at any point as long as it is remembered that the one-third point of the source is the zero-potential point when related to the 3-phase circuit.

Appendix II. Modified Equivalent Circuit for the Generalized Capacitance Condition

The circuit of Fig. 6 may be further simplified by the application of Thévenin's theorem to the circuit in such a manner as to replace the network between the load side of the switch and ground. If it is defined that

$$R = \frac{C_1}{C_0}$$

$$K = (R-1)$$

$$M = \frac{X_L}{X_{C1}}$$

$$A = \frac{M}{2(M+R)}$$

then, on a 60-cycle basis, the load impedance between the switch terminal and ground is

$$X \text{ equivalent} = \left(\frac{A+AK+\frac{3}{2}+\frac{3}{2K}}{A+1+\frac{3}{2K}}\right)X_{C1}$$

Similarly, neglecting trapped charges, the voltage to ground on the load side of the open switch is

$$E_{\text{open}} = -\frac{E}{2}\left(\frac{2K}{2K+3}\right)\left(\frac{\frac{2}{3}K+1}{\frac{2}{3}K+1-M}\right)$$

This defines a circuit with a ground point somewhere between the terminals of a single-phase source since the equivalent voltage on the load side of the switch is in phase with the voltage on the source side of the switch. This ground point is now the only ground in the system, and it may be moved without influencing the conditions imposed on the switch. Moving ground to one terminal of the source voltage results in the circuit of Fig. 7.

It should be noted that the new equivalent circuit, while satisfying 60-cycle conditions, is not correct during transients since it has only one natural frequency oscillation while the exact equivalent circuit of Fig. 6 has two natural frequencies.

Discussion

E. W. Boehne (Massachusetts Institute of Technology, Cambridge, Mass.): The authors have presented a much-needed study of the voltages and currents associated with the switching of capacitive circuits. One is impressed with the growing need for the analysis of the resistance-inductance-capacitance circuit, lumped and distributed, in connection with power field. Many of the problems which we are approaching were encountered by the communication engineer, working in the higher frequency domain, quite a few years ago.

The essential plea of this discussion is to encourage the inclusion in AIEE papers of sufficient straightforward circuit analysis so as to bridge the gap from theory to practice and hence make it possible for the young graduate to understand and become interested in modern power problems. The need for an elaborate transient analyzer board study to explore the range of parameters as presented to arrive at the spread from $3E$ to $2E$ for the voltage across the first pole to open under various conditions is questioned. Using the current nomenclature of C_1 and C_0 as described in the paper, equation 1 gives these results in a straightforward classical manner, namely

$$e = E\left(\frac{3C_1}{2C_1+C_0}\right)(1-\cos\omega t) \qquad (1)$$

When $C_0=0$ then e becomes maximum at $3E$. When $C_1=2C_0$ then e becomes maximum at $2.4E$. When $C_1=C_0$ then e becomes maximum at $2E$.
